3.1 Neuroendocrine Regulation of Insect Ecdysis

D Zitnan, Slovak Academy of Sciences, Bratislava, Slovakia
M E Adams, University of California, Riverside, CA, USA

3.1.1. Introduction

Insects are the dominant terrestrial life forms on earth. Their impressive evolutionary success is in no small measure a consequence of unique developmental and reproductive strategies, which have facilitated efficient resource exploitation and radiation into a wide range of ecological niches (Truman and Riddiford, 2002). Developmental strategies are most remarkable in the holometabolous insects where, as vermiform larvae, they are essentially mobile digestive systems, optimized for a wide range of food resources. The complete morphological transformation from vermiform larva to flying adult (metamorphosis) in many ways represents the birth of a new organism within the same life cycle, and enables the same species to minimize intraspecific

competition by occupying separate ecological niches. The remarkable ability of insects to change form during the life cycle, to enter dormancy at various stages of development, and to adapt to environmental changes via polyphenism, is made possible by the processes of molting and ecdysis.

Each stage of insect development is characterized by an alternation between feeding and molting, the latter culminating in ecdysis. During this intricate process, insects shed the old cuticle surrounding the external surface, and the lining of the foregut, hindgut, and tracheal tubes of the respiratory system. While ecdysis is the gateway to the next developmental stage, it also is effectively a life-threatening process, since failure to execute the sequence on schedule can result in death of the organism. Its success depends on coordinated gene expression controlled by ecdysteroids and juvenile hormones responsible for the formation of new cuticle and other tissues appropriate for the next stage. Ecdysteroids also participate in assembly of a peptide signaling cascade that regulates the ecdysis sequence at the end of the molt.

3.1.1.1. The Molt Cycle

Upon hatching from the egg, growth through successive immature stages culminates in the winged, reproductive adult, exquisitely adapted for dispersal and proliferation of new young. At the beginning of each larval instar, the animal feeds and grows until it acquires the proper size and nutritional state. The feeding stage or "intermolt" proceeds until integrative processes in the brain produce a decision to move on to the next stage, whereupon production and release of ecdysone occurs. The appearance of elevated ecdysteroid levels brings an end to the intermolt and onset of the molt associated with production of new cuticle (Figure 1). At the end of the last larval instar, holometabolous insects empty their guts and engage in wandering behavior aimed at finding an optimal location for pupation. Metamorphosis is initiated in pharate pupae (pupal development) and continues after pupation (adult development). This very complex process involves remodeling or programmed cell death of larval organs (see **Chapter 2.5**), and the proliferation of new cells and tissues specific for pupal and adult stages. In spite of these dramatic changes, it seems likely that basic mechanisms controlling larval, pupal, and adult ecdyses may be essentially similar or only slightly modified.

The critical endocrinological signal that switches the animal from feeding to molting is the elevation of ecdysteroids, including ecdysone, 20-hydroxyecdysone (20E), and other hydroxylated analogs of ecdysone (see **Chapter 3.3**), depending on the insect. Epidermal cells respond by changing shape and expressing a set of genes that prepare the animal for passage to the next stage. An early manifestation of this process is detachment of the epidermal cell layer from the existing cuticle, or apolysis, whereupon synthesis of a new cuticle layer appropriate for the next stage begins. Secretion of enzymatic molting fluid by the epidermal cells dissolves inner layers of the old cuticle so that its unsclerotized chitin and protein components can be recovered and recycled

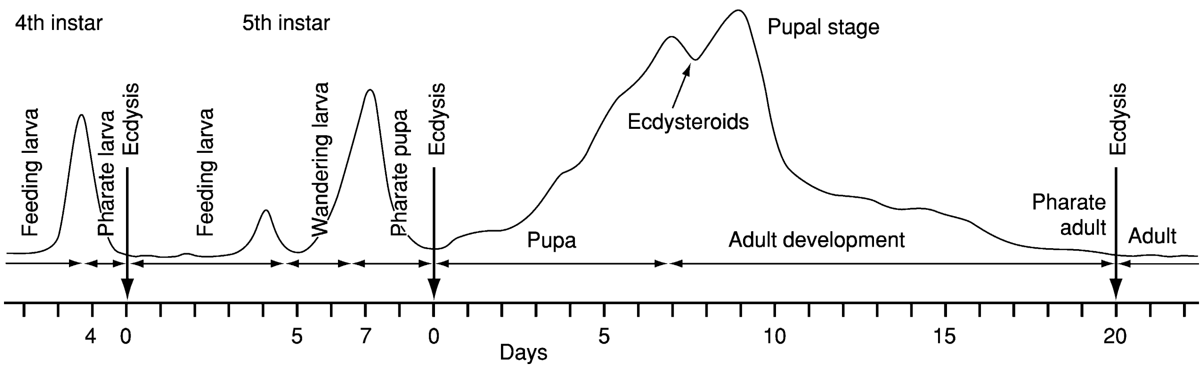

Figure 1 Ecdysteroid levels in hemolymph during development of *Manduca*. Ecdysteroid levels are low during feeding stages, but their levels increase about 30 h before ecdysis, larvae of the 4th instar stop feeding and develop a new cuticle (pharate 5th instar larvae). After ecdysteroid levels decline, pharate larvae ecdyse to 5th instar (day 0) and resume feeding on days 1–4. A small ecdysteroid peak on day 4 or 5 induces wandering stage (larvae stop feeding and move to a suitable pupation site). Large ecdysteroid peak induces pupal development on days 7–9 (pharate pupae) and after ecdysteroids decrease, animals pupate (day 0). Subsequent elevated ecdysteroid levels control adult development. (Normalized ecdysteroid levels are adapted from Zitnan, D., Ross, L.S., Zitnanova, I., Hermesman, J.L., Gill, S.S., *et al.*, **1999**. Steroid induction of a peptide hormone gene leads to orchestration of a defined behavioral sequence. *Neuron 23* (3), 523–535 (4th instar larvae), Zitnanova, I., Adams, M.E., Zitnan, D., **2001**. Dual ecdysteroid action on the epitracheal glands and central nervous system preceding ecdysis of *Manduca sexta. J. Exp. Biol. 204* (Pt 20), 3483–3495 (5th instar larvae); and Bollenbacher, W.E., Smith, S.L., Goodman, W., Gilbert, L.I., **1981**. Ecdysteroid titer during larval–pupal–adult development of the tobacco hornworm, *Manduca sexta. Gen. Comp. Endocrinol. 44* (3), 302–306 (pupal stage).)

into new cuticle or other tissues. Similarly, the old cuticular lining of the tracheal tubes detaches from underlying epidermal cells and the gap between these layers is filled with molting fluid. This fluid is later reabsorbed from the old head capsule and space between the old and new cuticles, while the new tracheal tubes become inflated with air.

Apolysis begins the "pharate" stage, defined as the incipient new animal covered by its old shell. Thus, a pharate 5th instar larva has already produced a new cuticle, but is still wearing its old coat from 4th instar. A pharate pupa is a developing pupa still encased in its old larval cuticle. A pharate adult has developed an adult phenotype, but is still covered by its old pupal cuticle.

As described in this review, the rise and fall of ecdysteroid levels induce sequential bouts of gene expression, resulting in the production of peptides and their receptors, peptide processing enzymes, and signal transduction proteins. These events ensure the activation and proper timing of processes that underly the upcoming ecdysis sequence, which involves air swallowing, tracheal dynamics, and a series of behaviors that culminates in cuticle shedding. The order of these events and their precise timing are determined by a peptide and neurotransmitter signaling cascade.

The molt cycle can be considered according to the following sequential steps:

1. Feeding and growth, which begins shortly after ecdysis of the previous stage.
2. Initiation of the molt induced by increased ecdysteroid levels in concert with juvenile hormones (see **Chapter 3.7**) to regulate gene expression important for development of the next stage phenotype, including the formation of new cuticle and tissues and synthesis of regulatory molecules.
3. The ecdysis sequence regulated by a decline in steroid levels and secretion of peptide hormones.
4. Termination of the molt during postecdysial processes characterized by expansion, sclerotization, and melanization of the new cuticle (see **Chapters 4.2**, **4.3**, and **4.4**) important for a definitive shape of the new developmental stage.

3.1.1.2. Regulation of the Ecdysis Sequence by a Peptide Signaling Cascade

An endocrine basis for ecdysis was demonstrated over 30 years ago through a series of classic brain transplantation experiments in giant silkmoths (Truman and Riddiford, 1970). These animals display "gated" circadian eclosion rhythms, meaning that adults may eclose only during a certain time of day when the gate is "open." Once the gate is closed, adult ecdysis (eclosion) is delayed until the next day. Eclosion gating was abolished by surgical removal of the brain, but could be re-established by implantation of the loose brain into the body cavity of the animal. Even more astounding, swapping brains between two species of moths that eclose at different times of day led to recipient moths following the eclosion schedule of the donor brain. This elegantly demonstrated two things: the existence of a timing device in the brain and the fact that the brain (see **Chapters 3.11** and **4.11**) acts as an endocrine organ by secreting a hormonal factor(s) that initiates eclosion. These experiments were reminiscent of the historic Kopec experiments, where transplantation of brains in moths was used to demonstrate an endocrine basis for the molt (Kopec, 1917, 1922). Eventually, a 62 amino acid peptide was identified as eclosion hormone (EH), which induces eclosion upon injection into pharate adults (Truman, 1992). Implicit in this work is the assumption that EH both initiates ecdysis or eclosion and is responsible for the gated nature of this behavior.

Our understanding of the complexity of signaling underlying ecdysis has grown considerably in recent years. That EH is not the sole initiator of ecdysis was demonstrated through discovery of the epitracheal endocrine system and Inka cells, which secrete pre-ecdysis triggering hormone (PETH) and ecdysis triggering hormone (ETH) into the hemolymph (Zitnan *et al.*, 1996; Ewer *et al.*, 1997; Kingan *et al.*, 1997a; Zitnan *et al.*, 1999). PETH and ETH act directly on the central nerrous system (CNS) to activate specific neuronal circuits for pre-ecdysis and ecdysis (Adams and Zitnan, 1997; Zitnan *et al.*, 1999; Zitnan and Adams, 2000; Zitnan *et al.*, 2002). It is likely that PETH and ETH trigger release of numerous peptides within the CNS, including EH, crustacean cardioactive peptide (CCAP), and others to coordinate the sequence of pre-ecdysis, ecdysis, and postecdysis behaviors (Ewer *et al.*, 1997; Gammie and Truman, 1999; Zitnan and Adams, 2000). Recent evidence indicates that additional neuropeptides including corazonin, FLRFamides, and myoinhibitory peptides (MIPs) also are involved in orchestration of the ecdysis sequence (Miao *et al.*, 1998; Davis *et al.*, 2003; Kim *et al.*, 2004).

Publication of the *Drosophila* genome (Adams *et al.*, 2000) has opened a new era of opportunity for elucidation of the peptide cascade controlling ecdysis. Further studies focusing on identification of target cells and organs producing G protein-coupled receptors (GPCRs) (see **Chapter 5.5**) for ecdysis

peptides and understanding of signal transduction induced by ligand–receptor binding will provide new insights into activation of the ecdysis sequence.

3.1.1.3. Chapter Overview

In this chapter, the current knowledge of the neuroendocrine basis for ecdysis, focusing on cellular and chemical signaling mechanisms that control gene expression prior to its initiation, and its timing and proper execution is reviewed. With regard to ecdysteroid regulated gene expression, the focus is on developmental events that create the peptidergic signaling framework underlying activation and execution of the ecdysis sequence. Regarding the ecdysis sequence itself, emphasis is given to peptide hormones and neuromodulators, which coordinate steps leading to shedding of the cuticle, including swallowing behaviors, tracheal dynamics, and pre-ecdysis, ecdysis, and postecdysis behaviors. Ultimately, a truly mechanistic analysis of ecdysis will depend on understanding its molecular basis. Because emphasis is placed on the neuroendocrine basis of ecdysis, many details of ecdysis in different stages and orders of insects are not covered in depth. Most of the discussion is centered around the moths *Manduca* and *Bombyx*, and the fruit fly *Drosophila*. Where possible, immunohistochemical demonstration of homologous cellular substrates for ecdysis in different insect phyla is presented, since such information may help to guide future research in these groups. For aspects of ecdysis not covered in this chapter, the reader is referred to a recent review on ecdysis (Ewer and Reynolds, 2002).

Section 3.1.2 characterizes the peptides implicated in ecdysis control, and the cells producing them. PETH, ETH, EH, and CCAP already are strongly implicated as causal signals in ecdysis, and the authors anticipate future progress in the field by summarizing what is known about peptides recently implicated in ecdysis regulation, including MIPs, corazonin, FLRFamides and ion transport peptides (ITPs). Only in the past few years have receptors for ecdysis peptides been discovered, made possible through the publication of organismal genomes, principally *Drosophila* and human. Section 3.1.3 therefore summarizes recent discoveries of G protein-coupled receptors for ecdysis peptides. Section 3.1.4 examines the role of gene expression in creating the signaling system underlying ecdysis, and how sequential gene expression ensures the proper timing of ecdysis initiation. Section 3.1.5 describes how a combination of factors contribute to ETH release from Inka cells, and Section 3.1.6 examines the peripheral and central factors involved in orchestration of pre-ecdysis and ecdysis motor programs. Section 3.1.7 presents a mechanistic model for endocrine control of the ecdysis sequence and summarizing statements.

3.1.2. Peptidergic Signals in Ecdysis

3.1.2.1. Introduction

During the past 10 years, the number of peptides implicated in ecdysis control has increased considerably. EH was the first peptide identified as an ecdysis initiator, and it is now thought to function both as a circulatory hormone and a neuromodulator within the CNS. A well-documented circulatory role for EH is to release ETHs from Inka cells. Circulating ETH acts directly on the CNS to initiate a neuropeptide cascade that regulates sequential steps in the ecdysis sequence. Included in the downstream cascade is the release of EH both into the hemolymph and within the CNS. Thus, EH and ETH engage in a positive feedback loop to ensure complete depletion of ETH from Inka cells. ETH also initiates tracheal inflation in *Drosophila* prior to the onset of ecdysis behaviors. The ability of ETH to trigger tracheal dynamics and behaviors depends on downstream peptides released from and within the CNS.

The list of peptides involved in ecdysis regulation continues to grow. One is CCAP, released centrally to activate ecdysis motor patterns in *Manduca*. In addition to CCAP, ITPs, MIPs, corazonin, and FLRFamide-related peptides are becoming recognized as putative ecdysis signals. The following sections summarize current knowledge on the properties of these peptides, their cellular origins, and likely functions in ecdysis regulation.

It is worth mentioning that many of these peptides were discovered years ago through the use of facile bioassays such as heartbeat and gut contraction. The names crustacean cardioactive peptide, corazonin, myoinhibitory peptides, and myosuppressins reflect the biological activities of peptides discovered in this manner. However, it is increasingly recognized that these names may not necessarily represent the authentic or most important physiological functions of these peptides. It is possible if not likely that many of these peptides are central neuromodulators involved in behaviors and other physiological functions that are associated with developmental processes such as ecdysis. It also seems likely that many peptides are multifunctional, carrying out some signaling functions not only as circulatory hormones, but also as transmitters and/or neuromodulators through release at or near synapses within the CNS.

3.1.2.2. Ecdysis Triggering Hormones

3.1.2.2.1. Epitracheal glands and Inka cells The first observations of epitracheal glands were published in the early part of the last century using *Bombyx mori* (Ikeda, 1913). These glands, which appear to have both endocrine and exocrine functions, remained unnoticed for almost 80 years, until they were rediscovered on histological sections of pharate larvae of the waxmoth *Galleria mellonella* during a search for peptidergic cells using an antiserum to FMRFamide (Zitnan, 1989). Nine pairs of segmentally distributed glands were found to be closely associated with the tracheal system and spiracles. One pair of glands is attached to tracheae near each prothoracic spiracle and eight pairs of glands are located on tracheae close to each abdominal spiracle (**Figure 2a**). Only the largest cell of each epitracheal gland shows FMRFamide-like immunoreactivity (IR), while 2–3 other cells are not stained (**Figure 2b**; Zitnan, 1989). Ultrastructural studies of epitracheal glands revealed numerous electrodense droplets in the largest gland cell of pharate pupal *B. mori*, which degenerate in freshly ecdysed pupae, but their function was not determined (Akai, 1992). Further immunohistochemical studies with antisera to horseradish peroxidase (HRP) and small cardioactive peptide B (SCP_B) showed that each epitracheal gland of *M. sexta* is composed of one prominent peptidergic cell and 2–3 smaller cells. The smaller cells degenerate after pupation, leaving only nine pairs of large peptidergic cells in developing adults. The large endocrine cells show strong SCP_B-IR in pharate larvae, pupae, and adults, but peptide staining disappears after each ecdysis, indicating that these cells release their contents into the hemolymph (Zitnan *et al*., 1996). These remarkable peripheral endocrine cells were named Inka cells in honor of a beautiful fairy from the Tatra mountains.

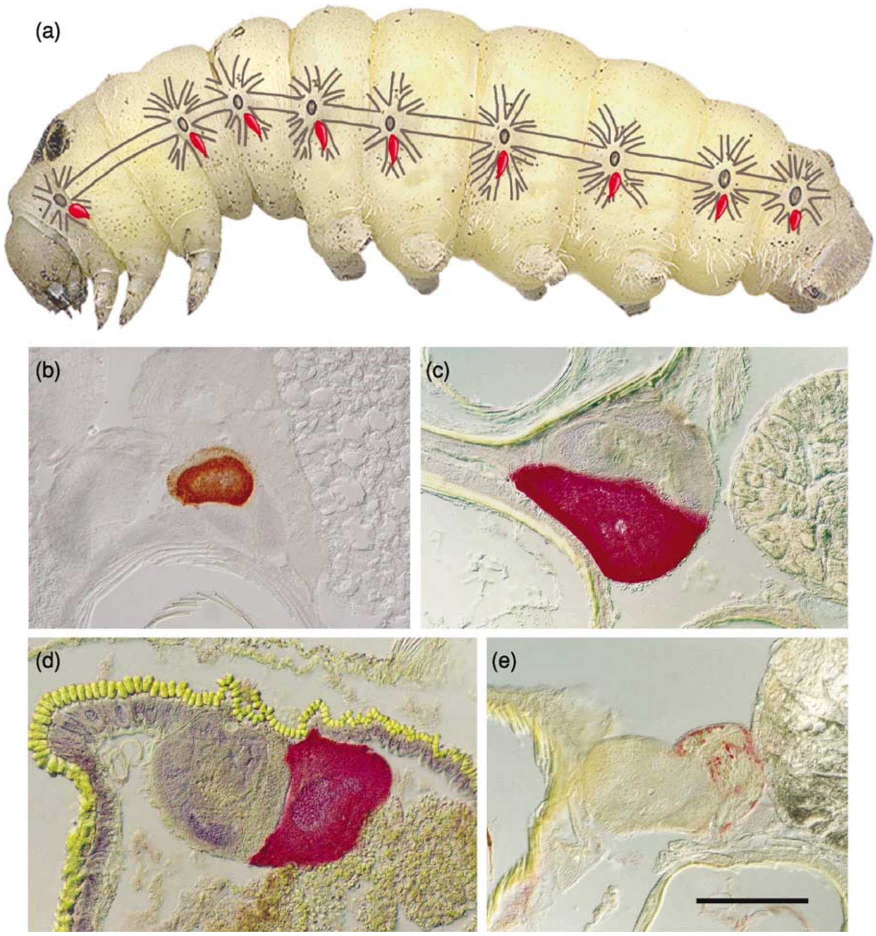

Figure 2 Distribution and peptide immunoreactivity (IR) of Inka cells in the moths *B. mori*, *G. mellonella*, and *M. sexta*. (a) Schematic drawings of Inka cells attached to the tracheal system of *Bombyx* pharate pupa. One prothoracic and eight abdominal Inka cells are attached to lateral tracheae near each spiracle. Another set of corresponding cells is located on the opposide side of the body. (b) The peptidergic nature of Inka cells was first identified with antiserum to FMRFamide in the waxmoth, *Galleria*. (c–e) Strong PETH-IR (c) and ETH-IR (d) in Inka cells of *Manduca* pharate pupae disappears at the onset of ecdysis (e). Scale bar = 150 μm.

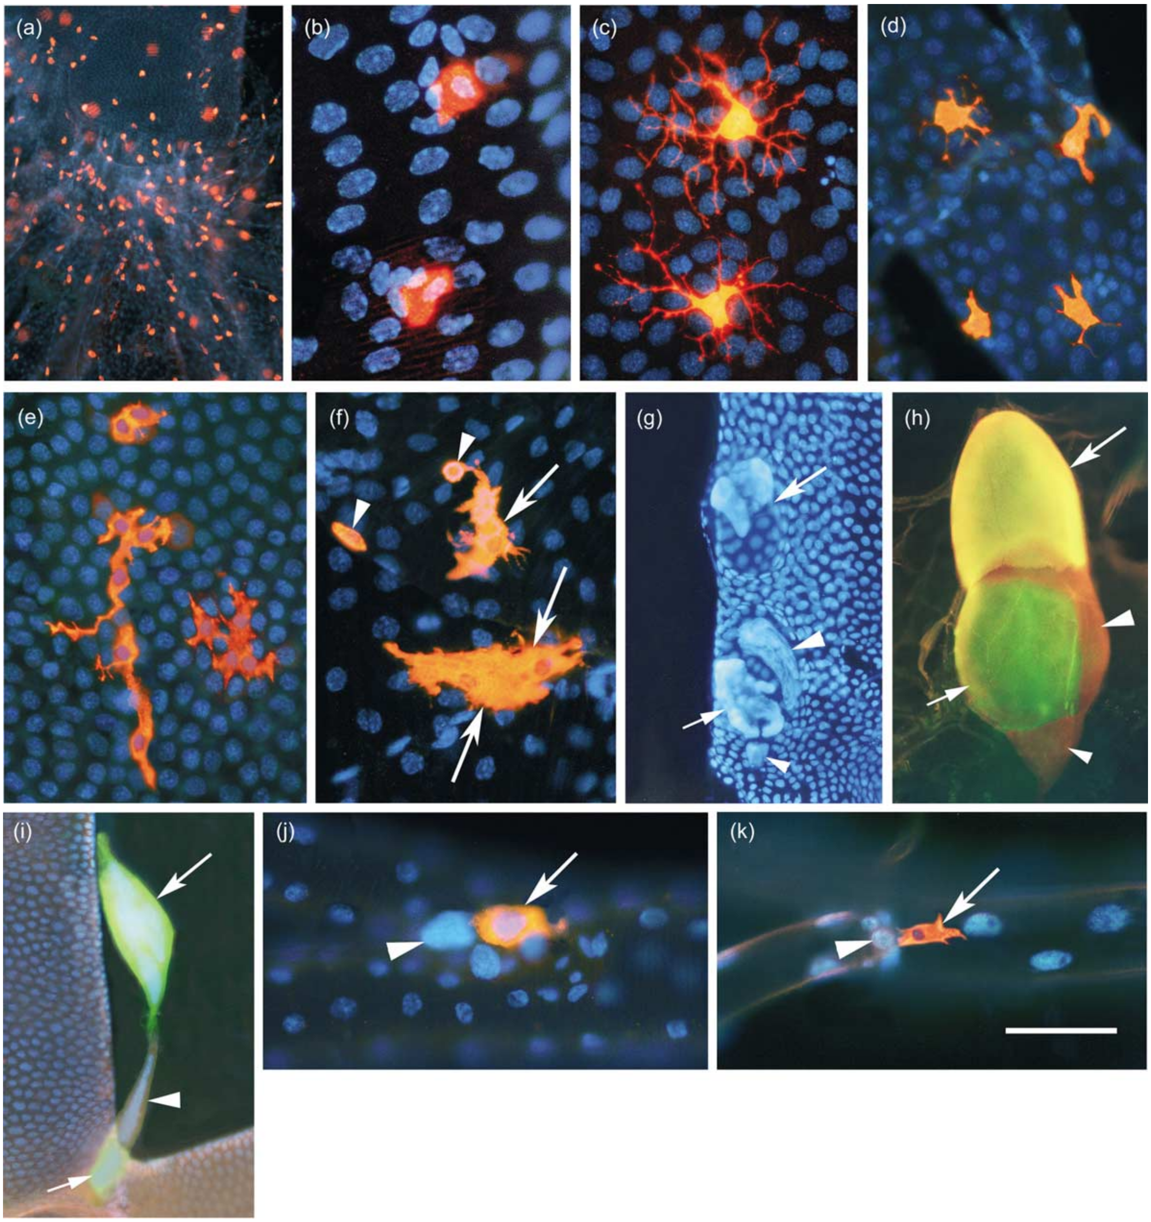

Figure 3 Variability of Inka cells in different insect species. (a–f) Immunohistochemical staining with PETH antiserum shows that all hemimetabolous and most holometabolous insects contain small Inka cells (stained orange–red or yellow), which are scattered throughout the surface of the entire tracheal system (nuclei are stained blue with diamino-phenylindole; DAPI). (a) PETH-IR (stained orange–red) in thousands of small Inka cells of the dragonfly *Sympetrum* sp. (b) Inka cells of the cockroach *N. cinerea* are simple and oval, whereas the cricket *A. domestica* (c) contains cells with prominent cytoplasmic processes. (d) Numerous Inka cells with narrow processes are distributed on narrow tracheae of the bug *Pyrrhocoris apterus*. (e) The water beetle *Laccophilus* sp. contains groups of 2–4 Inka cells with thick processes. (f) Two types of cells are present in the mealworm beetle *Tenebrio molitor*; groups of larger single or coupled Inka cells are located on major tracheae close to spiracles (arrows), whereas single small cells are distributed throughout narrower branching tracheae (arrowheads). (g–i) Large epitracheal glands containing Inka cells in *Manduca* and *Bombyx*. (g) DAPI nuclear staining shows that each *Manduca* epitracheal gland is composed of the prominent Inka cell (large arrow), narrow cell (large arrowhead), exocrine cell (small arrow), and canal cell (small arrowhead). (h,i) Double immunohistochemical staining with antisera to PETH and HRP reveals that only Inka cells of *Manduca* (h) and *Bombyx* (i) produce peptide hormones (yellow, large arrow). The exocrine cells are only stained with HRP antiserum (green, small arrow), while the other two cells are not labeled (large and small arrowheads). (j,k) PETH-IR in Inka cells (stained orange–red, arrows) of the cranefly, *Tipula* (j) and *Drosophila* (k). Note that other small cells of epitracheal glands show no PETH-IR (arrowheads). Scale bar = 200 μm in (a); 50 μm in (b–k).

Subsequent investigations demonstrated that Inka cells produce PETH and ETH, peptide hormones that activate pre-ecdysis and ecdysis motor programs in the CNS (**Figure 2c–e**).

Ultrastructural studies of epitracheal glands in *Lymantria dispar* showed that each gland contains four cells, named as follows: type I endocrine cell (Inka cell homolog), type II endocrine cell, exocrine cell, and canal cell (Klein *et al*., 1999). Inka cells release their hormonal content at ecdysis, but secretion of type II endocrine cells was not observed and their endocrine function requires confirmation by other techniques. As described in *Lymantria*, *Manduca* epitracheal glands contain an exocrine cell, which projects a duct through the canal cell into the lumen between new and old tracheae (Zitnanova *et al*., 2001). The apparent size decrease of the exocrine cell in freshly ecdysed larvae and pupae indicates that the cell's content is released into the tracheal lumen, possibly to aid shedding of the old tracheae during ecdysis.

The widespread occurrence of Inka cells in insects has been demonstrated by immunohistochemistry using an antiserum against PETH. Using this approach, Inka cells were observed to occur in 40 representatives of diverse insect orders (Zitnan *et al*., 2003). Surprisingly, two patterns of Inka cells were found. In most insect orders, hundreds or thousands of Inka cells of various sizes and shapes are scattered throughout the tracheal surface (**Figure 3a–f**). This contrasts sharply with the pattern described originally in certain holometabolous insects, where a well-defined system of 16–18 pairs of segmental epitracheal glands occurs, each with a single, prominent Inka cell associated with 2–4 other cells (**Figure 3g–k**; Zitnan *et al*., 2002, 2003). Numerous small, round Inka cells were stained in the dragonfly *Sympetrum* sp. (**Figure 3a**), and similar cells were found in the apterygote silverfish *Lepisma saccharina* and primitive aquatic insects–mayflies and damselflies. Two distinct cell types were found on different tracheae of the cockroach *Nauphoeta cinerea*; oval Inka cells were found on the major segmental tracheae (**Figure 3b**), while cells with cytoplasmic processes were stained on thin tracheae of the gonads and gut. Simple oval Inka cells also are found in the cockroach *Periplaneta americana* and the locust *Locusta migratoria*, whereas cells with prominent cytoplasmic processes are detected in cockroaches *Blabera craniifera* and *Phylodromica* sp., the cricket *Acheta domestica* (**Figure 3c**), the stonefly *Perla* sp., and bugs *Pyrhocoris apterus* (**Figure 3d**) and *Triatoma infestans*.

Inka cells of holometabolous insects also can be quite variable. Numerous, single Inka cells dispersed throughout the tracheae are found in the alderfly *Sialis* and the antlion *Myrmeleon*. Variability of Inka cells in representatives of several beetle species reflects the enormous diversity of this large insect group. For example, the water beetle *Laccophilus* sp. contains coupled elongated Inka cells with short cytoplasmic processes (**Figure 2e**), but the mealworm beetle *Tenebrio molitor* has two distinct types of Inka cells: groups of 2–6 larger cells that are attached to tracheae near each spiracle, and small cells scattered throughout the tracheal surface (**Figure 3f**). Numerous small Inka cells of various shapes are found in other beetles, but only nine pairs of large Inka cells associated with epitracheal glands are present in the Colorado potato beetle, *Leptinotarsa decemlineata* (for details see Zitnan *et al*., 2003). Similar epitracheal glands occur in most investigated hymenopterans, and all lepidopterans and dipterans. The only exception is the honeybee *Apis mellifera*, which contains a large number of small Inka cells (Zitnan *et al*., 2003). Variability of epitracheal glands containing prominent Inka cells is depicted in moths *Manduca* and *Bombyx*, the crane fly *Tipula* sp., and fruit fly, *Drosophila melanogaster* (**Figure 3g–k**).

Strong PETH-IR detected in representatives of both hemi- and holometabolous insects before ecdysis disappears after each larval, pupal, and adult ecdysis. This suggests that Inka cells release their hormonal content into the hemolymph to initiate and regulate shedding of the old cuticle. Inka cells of hemimetabolous insects appear to degenerate after adult ecdysis as indicated by permanent disappearance of PETH-IR on tracheal surfaces, whereas Inka cells in some representative holometabolous insects (beetles, moths, and dipterans) persist in adults and continue to produce peptide hormones related to PETH and ETH. Release and function of these peptides in adults has not been examined to date (Zitnan *et al*., 2003).

3.1.2.2.2. Ecdysis triggering hormones in lepidoptera A physiological function for epitracheal glands and identification of an active peptide hormone were first described in *Manduca sexta* (Zitnan *et al*., 1996). Injection of epitracheal gland extracts into *M. sexta* pharate larvae induced within 5–10 min the ecdysis behavioral sequence. Exposure of the isolated CNS *in vitro* to the same extracts produced corresponding motor bursts (see Section 3.1.5.1 for details). Saline extracts of 50 glands from four pharate pupae were separated by a single step of high-performance liquid chromatography (HPLC). Biological activity identical to that of the gland extract was found associated with a linear, 26 amino acid, C-terminally amidated peptide (mol. wt. 2940)

(**Figure 4**). This peptide was named *Manduca* ecdysis triggering hormone or Mas-ETH (Zitnan *et al*., 1996). Injection of synthetic ETH mimicked the effects of the native peptide. A similar peptide (mol. wt. 2656), with a three amino acid deletion near the N-terminus subsequently was isolated from Inka cells of pharate pupal *B. mori* and called Bom-ETH (**Figure 4**; Adams and Zitnan, 1997). Either peptide is sufficient to induce the ecdysis sequence upon injection *Manduca* or *Bombyx* pharate larvae.

Identification of the cDNA precursor and gene encoding ETH in *Manduca* revealed two additional peptides produced by Inka cells (**Figure 5**). One of these, an 11 amino acid, C-terminally amidated peptide (mol. wt. 1269), was subsequently isolated from epitracheal gland extracts by HPLC and synthesized. Since this peptide induced only pre-ecdysis behavior in *Manduca*, it was named pre-ecdysis triggering hormone (PETH; Zitnan *et al*., 1999). The third peptide, composed of 47 amino acids with a free C-terminus, was also synthesized, but showed no obvious biological function upon injection into pharate larvae. It was therefore named ETH-associated peptide or ETH-AP (mol. wt. 5658). Significant levels of partially processed precursor peptides corresponding to PETH-ETH (PE; mol. wt. 4407) and ETH-ETH-AP (EA; mol. wt. 8953), along with the entire, unprocessed precursor PETH-ETH-ETH-AP (PEA; mol. wt. 10419) were also isolated directly from Inka cells by HPLC. The ETH precursor thus contains one copy each of PETH, ETH, and ETH-AP (Zitnan *et al*., 1999). A similar precursor structure and corresponding peptides occur in *B. mori* (Zitnan *et al*., 2002).

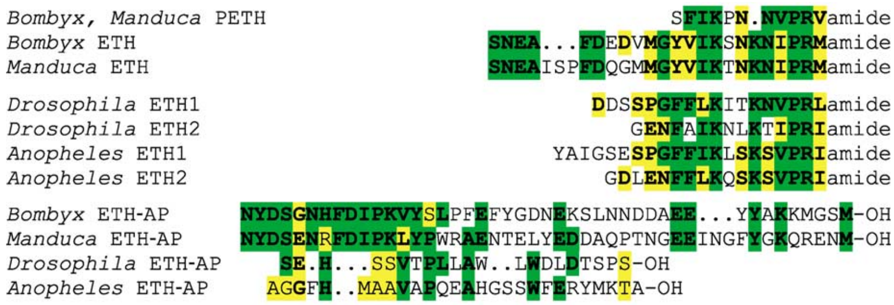

Figure 4 Amino acid sequences of PETH, ETH, and ETH-AP of moths and dipterans. Green represents sequence identity, yellow sequence similarity.

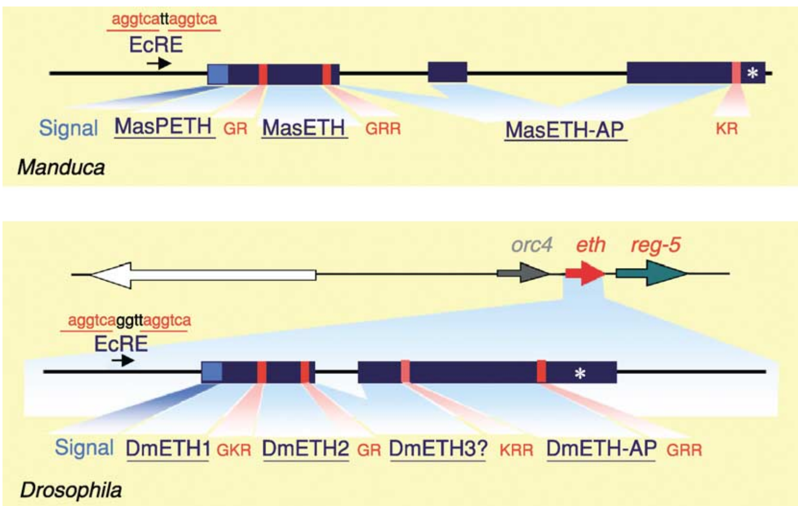

Figure 5 Similarity in the organization of *Manduca* and *Drosophila* genes encoding ETH. The *Manduca* ETH gene consists of a signal sequence, followed by one copy each of MasPETH, MasETH, and MasETH-AP. An upstream direct repeat ecdysone response element (EcRE) is a putative steroid receptor binding site for regulation of the gene. The Mas-ETH-AP sequence is interrupted by two introns. The signal sequence of *Drosophila eth* is followed by one copy each of DrmETH1 and DrmETH2. An upstream EcRE is also present in this gene. The sequence immediately downstream of DrmETH2 is designated DrmETH-AP1. Its sequence is followed by a second much larger peptide designated DrmETH-AP2. The gene *eth* occurs on the second chromosome right arm 60E1-2; see Zitnan *et al*. (1999), Park *et al*. (1999), and Park and Adams (unpublished data) for details.

Candidate regulatory elements contributing to ETH expression were revealed through identification of promoter regions in the ETH genes of moths and flies (**Figure 5**). Among the elements observed are direct repeat motifs thought to function as ecdysone response elements (EcRE). In *Manduca*, the direct repeat AGGTCATTAGGTCA and elements of Broad Complex are present in the ETH gene promoter (Zitnan *et al*., 1999). A similar sequence occurs in the *Drosophila eth* promoter: AGGTCAggttAGTTCA (Park *et al*., 1999). Such EcRE are known to bind the ecdysone receptor-ultraspiracle (EcR-USP) heterodimer in *Drosophila* and mosquitos (Vogtli *et al*., 1998; Wang *et al*., 1998) (see **Chapter 3.5**), and seem likely to function in the transcriptional regulation of ETH gene expression.

Immunohistochemical staining with antisera specific to ETH and ETH-AP show that these peptides are produced only in Inka cells of *Manduca* and *Bombyx* (Zitnan *et al*., 1999, 2002). The release of PETH and ETH into the hemolymph at each ecdysis was demonstrated by enzyme immunoassays and immunohistochemistry using antisera raised against PETH and ETH (Zitnan *et al*., 1999, 2002; Zitnanova *et al*., 2001). These studies demonstrated that during the initial 20 min of pre-ecdysis, low levels of these peptides (up to 5 nM) are present in the hemolymph, apparently in response to corazonin release (**Figure 6**; see Section 3.1.5.1). Hemolymph levels of PETH and ETH then rise sharply, reaching ~30 nM about 20 min later. This massive peptide secretion into the hemolymph correlates with elevation of 3′,5′-cyclic guanosine monophosphate (cGMP) in the Inka cell and depletion of its stores, probably in response to EH release (**Figure 6**; see Section 3.1.5.2). Initiation of ecdysis behavior only occurs after a 20 min delay, by which time peptide levels have subsided to ~15 nM (see Section 3.1.6.1.4 for details regarding this delay; Zitnan *et al*., 1999). Low levels of a partially processed precursor peptide (ETH-

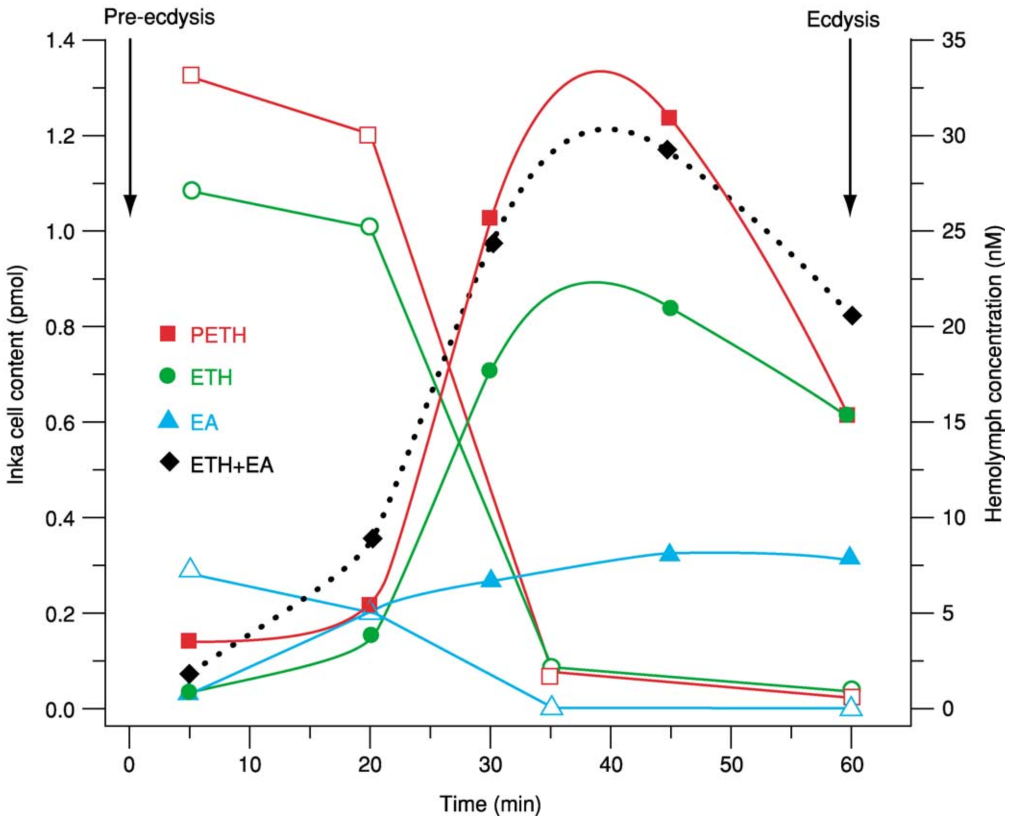

Figure 6 PETH and ETH levels in Inka cells and hemolymph during the ecdysis sequence. Low levels of PETH and ETH are present in the hemolymph (solid symbols) during the initial 20 min of pre-ecdysis. A sharp increase of *Manduca* Inka cell peptides in the hemolymph was detected about 20 min later. This is correlated with elevated cGMP levels and depletion of these peptides in Inka cells (open symbols). Hemolymph levels of PETH and ETH have decreased to about a half by the onset of ecdysis. Note that low levels of a partially processed precursor peptide ETH-ETH-AP (EA) are coreleased into the hemolymph. (Reprinted with permission from Zitnan, D., Ross, L.S., Zitnanova, I., Hermesman, J.L., Gill, S.S., *et al.*, **1999**. Steroid induction of a peptide hormone gene leads to orchestration of a defined behavioral sequence. *Neuron 23* (3), 523–535; © Elsevier.)

ETH-AP) also are co-released into the bloodstream along with fully processed peptides. The physiological significance of this precursor co-release, if any, is unclear.

3.1.2.2.3. Ecdysis triggering hormones in Diptera "In silico" screening using the nucleotide sequence encoding the *Manduca* ETH precursor led to identification of the *Drosophila eth* gene (Park *et al.*, 1999). This approach later was used to identify a similar gene in the mosquito *Anopheles gambiae* (Zitnan *et al.*, 2003). The *eth* gene of both dipterans encodes two related amidated peptides, ETH1 and ETH2, and a different nonamidated peptide ETH-AP (Park *et al.*, 1999; Park *et al.*, 2002a; Zitnan *et al.*, 2003). Recently, ETH-AP1 has been isolated from tracheal extracts of *Drosophila* (Schoofs, Clynen, Spalovská-Valachova, and Zitnan, unpublished data). Sequences of all peptide hormones and organization of the ETH gene of moths and dipterans are shown in **Figures 4** and **5**.

The N-terminal of ETH1 was deduced through algorithms designed for prediction of signal peptide cleavage sites in eukaryotic cells (Nielsen *et al.*, 1997). This prediction led to the assignment of ETH1 as a 18 amino acid peptide with N-terminal amino acids DDSSP-, but an alternative sequence consisting of 23 amino acids containing the N-terminal sequence AISQADDSSP-was also considered (Park *et al.*, 1999, 2002a; Zitnan *et al.*, 2003). These peptides were both prepared by chemical synthesis and compared in bioassays for potency in triggering adult eclosion. The data showed ETH1 (N-terminus DDSSP-) was at least 100 times more potent in triggering adult eclosion than the alternative peptide (N-terminus AISQADDSSP-). Subsequent mass spectometric analysis provided confirmatory evidence for the original sequence assignments for both ETH1 and ETH2 (**Figure 4**; Hermesman and Adams, unpublished data).

The *eth* gene in *Drosophila* is expressed only in Inka cells. This was demonstrated by producing a transgenic line of flies expressing the transgene *2eth3-egfp* (Park *et al.*, 2002a). The construct contains the upstream promoter and coding regions of the *eth* gene followed by the chimeric *egfp* gene encoding enhanced green fluorescent protein (EGFP). These flies show colocalization of ETH-IR and EGFP-IR in Inka cells (**Figure 7**); no other cells in the entire organism were stained in larvae and adults. Secretory activity of Inka cells was observed as a sharp decline of cellular EGFP fluorescence just before tracheal inflation and initiation of the ecdysis behavioral sequence in larvae (Park *et al.*, 2002a). These findings confirm that the ETH gene is expressed in Inka cell specific fashion, and that the peptides are released at the appropriate time just preceding ecdysis in flies.

An antiserum to mollusk myomodulin was used to stain "peritracheal myomodulin (PM) cells" in six insect species (O'Brien and Taghert, 1998). Double labeling with myomodulin and SCP_B antibodies indicated that PM cells were Inka cell homologs. These authors speculated that myomodulin-like peptide(s) were coreleased with ETHs to control different functions at ecdysis. However, no function for myomodulin has been determined and no myomodulin-like peptide has been identified in insects. Inka cells of moths and flies also show strong immunohistochemical staining with antibodies to several other neuropeptides (e.g., FMRFamide, PBAN, vasopressin; Zitnan *et al.*, 2003). These neuropeptides share conserved amidated sequence motifs (-RXamide or -PRXamide; X = I, L, M, V) with PETH and ETH, indicating that antisera to these neuropeptides cross-react with amidated C-termini of PETH and ETH. Indeed, cross-reactivity of myomodulin and FMRFamide antisera with PETH and ETH was confirmed by specific enzyme immunossays in HPLC-isolated extracts of *Manduca* epitracheal glands and in *Drosophila* and *Musca* tracheal extracts (Zitnan *et al.*, 2003). It was further demonstrated that Inka cells of mutant larvae lacking the *eth* gene failed to react with myomodulin antiserum, while strong staining was detected in Inka cells of control *Drosophila* larvae (Canton S) producing ETH (Zitnan *et al.*, 2003). These data demonstrate that Inka cells are highly specialized for production of peptide hormones expressed by the *eth* gene, and do not produce myomodulin- or FMRFamide-related peptides in moths and flies.

3.1.2.2.4. Conservation of ETH signaling in the insecta The presence and biological activity of ETH-related peptide hormones in Inka cells from various insects was tested by injection of *Bombyx* pharate larvae with tracheal extracts from the cockroach *Nauphoeta*, cricket *Acheta*, bug *Pyrrhocoris*, beetle *Tenebrio*, fly *Drosophila*, and mosquito *Aedes* (Zitnan *et al.*, 2003). These extracts induced pre-ecdysis within a few minutes followed in most instances by ecdysis behavior in *Bombyx* larvae. Extracts from *Nauphoeta*, *Acheta*, *Drosophila*, and *Aedes* were most active in this assay. These data suggest that the ETH signaling system is conserved in diverse insect groups and perhaps all insects.

Further searches for Inka cell peptides in hemimetabolous insects resulted in detection of PETH-immunoreactive peaks in HPLC purified tracheal

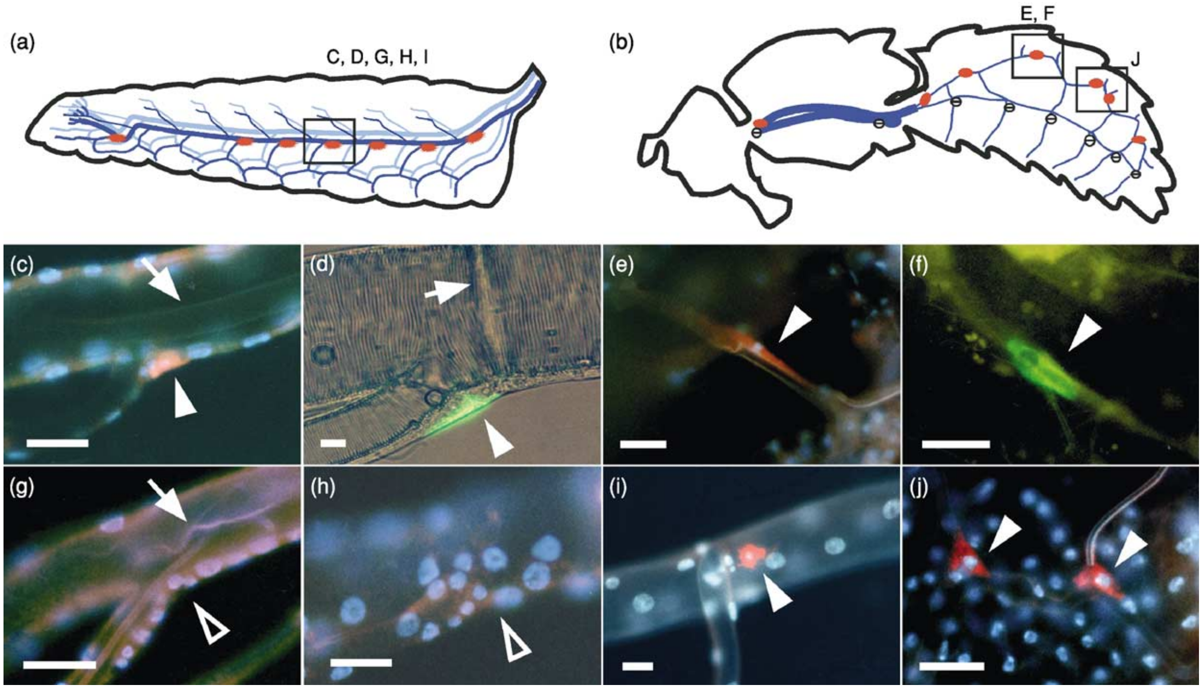

Figure 7 *Drosophila* Inka cell immunohistochemistry, EGFP expression in the *2eth3egfp* fly line, and loss of immunoreactivity in the deletion mutant *eth*[25b]. Red, blue, and green colors in photomicrographs are from Cy3, DAPI, and EGFP, respectively. Scale bar = 10 μm. (a) Diagram showing the larval tracheal system and positions of Inka cells (red). The cell expressing EGFP (arrowhead) at a node (arrow, see **Figure 1b**) is shown with low intensity transmitted light. (e) Cy3 staining in the adult stage using the DrmETH1 antibody. (f) Expression of the *eth3-egfp* transgene in late 3rd instar. (g) The *eth* deletion mutant *eth*[25b] Cy3 (late 1st instar) shows no immunohistochemical staining of the Inka cell. The collapsed old tracheal tube (arrow) is separated from new intima. The open arrowhead indicates location of the epitracheal gland in wild-type flies. (h) Depletion of ETH immunoreactivity in the Inka cell of wild-type flies (open arrowhead) immediately after ecdysis to early 2nd instar. (i) Immunoreactive Inka cell in the late 3rd instar using an antibody against MasPETH. (j) Inka cell immunoreactivity in the adult stage using the MasPETH antiserum. (Data from Park, Y., Filippov, V., Gill, S.S., Adams, M.E., **2002a**. Deletion of the ecdysis-triggering hormone gene leads to lethal ecdysis deficiency. *Development 129*(2), 493–503.)

extracts of *Nauphoeta* and *Pyrrhocoris*. Four immunopositive peaks were detected in extracts of *Nauphoeta*, whereas only two peaks were found in *Pyrrhocoris* (Zitnan *et al*., 2003).

3.1.2.3. Brain Ventromedial Cells and Eclosion Hormone

The role of EH in insect ecdysis has recently been reviewed in detail (Ewer and Reynolds, 2002). Here the focus is on highlights of EH biology relevant to this chapter. The endocrine control of ecdysis was demonstrated by Truman in classic experiments on adult emergence (referred to as "eclosion" in this stage). EH, located in the brain of giant silkmoths, was shown to be released into the circulatory system from the corpora cardiaca–corpora allata complex (CC–CA; Truman and Riddiford, 1970; Truman, 1971). Further studies showed that CC–CA extracts from pharate adults triggered premature ecdysis in pharate larvae, pupae, and adults upon injection into the hemocoel (Reynolds *et al*., 1979; Copenhaver and Truman, 1982; Truman, 1985).

After initial isolation and determination of the partial N-terminal sequence of EH in *Bombyx* (Nagasawa *et al*., 1983, 1985), its complete sequence was simultaneously identified in three laboratories from CC–CA or heads of *Manduca* and *Bombyx* pharate adults (Kataoka *et al*., 1987; Kono *et al*., 1987; Marti *et al*., 1987; Nagasawa *et al*., 1987). EH of both species is a closely related 62 amino acid peptide with three internal disulfide bonds (**Figure 8**; Terzi *et al*., 1988; Kono *et al*., 1990b; Kataoka *et al*., 1992). Soon thereafter, the cDNA and gene encoding EH were described in *Manduca*, *Bombyx*, and *Drosophila* (Horodyski *et al*., 1989; Kamito *et al*., 1992; Horodyski *et al*., 1993).

Immunohistochemistry using an antiserum against *Manduca* EH combined with physiological techniques was used to identify the source of EH. These approaches led to identification of a cluster of lateral neurosecretory cells (type Ia) in the brain, which showed "eclosion hormone" biological activity and immunoreactivity in *Manduca* pharate adults (Copenhaver and Truman, 1985, 1986a, 1986b, 1986c). However, *in situ* hybridization studies did not confirm EH expression in type Ia cells, but rather in two pairs of ventromedial cells now recognized as the authentic EH neurons (Horodyski *et al*., 1989). Independent studies have recently shown that a subset of these cells (type Ia_1) produces a neuropeptide corazonin (**Figure 9a** and **b**; Wise *et al*., 2002). Unexpectedly, injection of corazonin mimics the action of EH (see Section 3.1.5.2). Another subset of the lateral cells (type Ia_2) produces ion transport peptide (ITP) (**Figure 9c**; see Section 3.1.2.4; Spalovská-Valachova, Zitnan, Cho, Park, Adams, unpublished data). Interestingly, ITP shows a striking sequence homology with EH in one part of its primary structure, and it therefore seems possible that the EH antiserum used in previous studies may have cross-reacted with conserved regions of the ITP sequence (**Figure 8**).

Subsequent immunohistochemical studies in *Manduca* showed EH is produced by two pairs of the brain ventromedial neurosecretory cells (VM cells, type V, **Figure 9a**). These neurons project axons along the entire length of the ventral nerve cord, which exit the CNS via the proctodeal nerves to make neurohemal release sites on the hindgut surface

Figure 8 Comparison of EH and ITP/CHH sequences in insect and crustaceans. Green represents sequence identity, yellow sequence similarity.

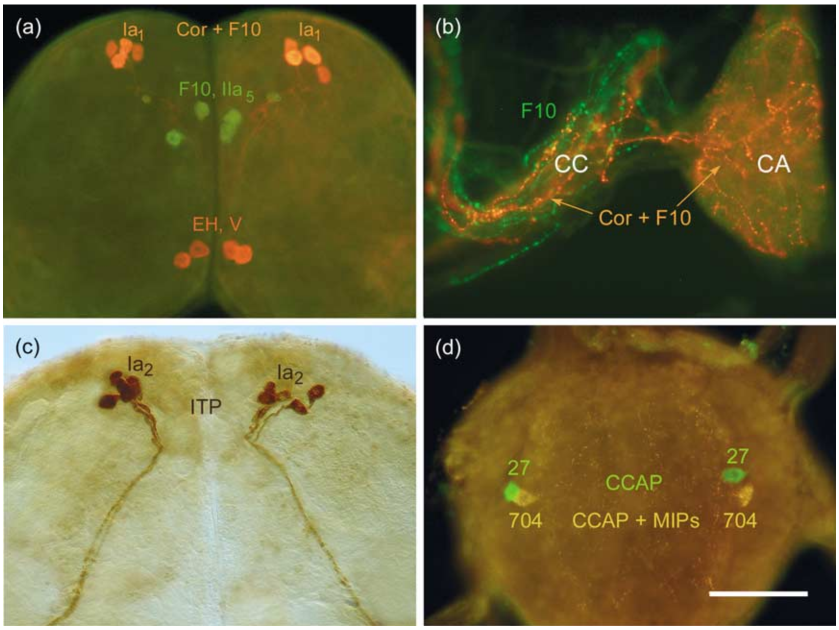

Figure 9 Peptidergic cells implicated in control of the ecdysis sequence in *Manduca*. (a) Triple immunohistochemical staining of a pharate 4th instar larva brain showing colocalization of corazonin and F10 in the ipsilateral neurosecretory cells (type Ia_1, orange color). F10 is also produced by medial neurosecretory cells (type IIa_5, green color), while EH is expressed in the ventromedial cells (type V, red color). (b) Corazonin and F10 produced by Ia_1 cells are stored in the axon terminals of entire corpora cardiaca and corpora allata complex (CC, CA; orange color, arrows), while F10 from medial cells IIa5 is mostly stored in the CC region (green color). (c) ITP-immunoreactivity in ipsilateral neurosecretory cells Ia_5. (d) Double staining with antisera to CCAP and MIP indicates that abdominal neurosecretory cells 27 produce only CCAP (green color), while interneurons 704 express both CCAP and MIPs (orange color). Scale bar = 100 μm.

(Truman and Copenhaver, 1989). During adult development they project additional axons to the CC, while axons running through the ventral nerve cord remain intact (Riddiford *et al.*, 1994). Similar pairs of VM cells have been identified in *Bombyx* with a monoclonal antibody to *Bombyx* EH (Kono *et al.*, 1990a). *In situ* hybridizations of the CNS in embryos, larvae, and developing adults, and Northern blots of different larval ganglia of the CNS confirmed that the gene encoding EH is only expressed in the brain VM cells (Horodyski *et al.*, 1989; Kamito *et al.*, 1992; Riddiford *et al.*, 1994). Similarly, *Drosophila* EH is expressed in a single pair of dorsomedial neurons projecting from the brain into the CC as well as posteriorly within the fused ventral ganglion (Horodyski *et al.*, 1993; Baker *et al.*, 1999).

Immunohistochemical staining with an antiserum raised against the C-terminus of *Manduca* EH revealed EH-immunoreactivity (EH-IR) in the CNS of diverse insect groups (**Figure 10**). These insects show EH-IR in a variable number of neurosecretory cells in the brain. For example, two pairs of ventromedial (VM) cells are present in the dragonfly *Sympetrum* sp., while a cluster of 4–10 EH-IR neurons is stained in the cockroach *Nauphoeta cinerea* and bug *Pyrrhocoris apterus*, and one pair of cells is found in the locust *L. migratoria* and cricket *A. domestica*. VM neurons of most species project nonarborizing axons posteriorly along the entire ventral nerve cord. Interestingly, axons of *Acheta* VM cells show obvious arborizations in the anterior and posterior regions of each ventral ganglion, and two additional pairs of lateral neurons are stained in these ganglia (**Figure 8c**). EH-producing neurons in most holometabolous insects examined resemble those described in *Manduca* (Truman and Copenhaver, 1989). Two pairs of VM neurons are present in alderfly *Sialis* sp., antlion *Myrmeleon* sp., mealworm beetle *T. molitor* and silkwmoth *B. mori*, while only one pair of dorsomedial neurons shows EH-IR in the fruitfly *Drosophila* (**Figure 10**).

Immunohistochemical staining and physiological experiments suggest that EH is released centrally from axons within ventral ganglia to participate in ecdysis activation (Hewes and Truman 1991; Baker *et al.*, 1999; Zitnan *et al.*, 2002), as well as peripherally to participate in the release of PETH and ETH from Inka cells and other functions (Kingan *et al.*, 1997a).

3.1.2.4. Ion Transport Peptides and Crustacean Hyperglycemic Hormones

Insect ITPs belong to a large family of peptides that are prominent in crustacean physiological functions: crustacean hyperglycemic hormones (CHHs), molt inhibiting hormones (MIHs), vitellogenesis inhibiting hormones (VIHs), and mandibular organ inhibiting hormones (MOIHs) (reviews: de Kleijn *et al.*, 1998; Van Herp, 1998; Webster, 1998; see also **Chapter 3.16**). As their names indicate, these large peptides regulate various functions including water homeostasis, energy mobilization, vitellogenesis, and biosynthesis of ecdysteroids and methyl farnesoate (Keller, 1992; Audsley *et al.*, 1992a, 1992b; Meredith *et al.*, 1996; Wainwright *et al.*, 1996; Liu *et al.*, 1997; Keller *et al.*, 1999).

Since some actions of CHH are associated with crustacean ecdysis, it is given emphasis here. CHH was originally identified in sinus gland extracts of *Carcinus maenas* as an amidated 72 amino acid peptide (Kegel *et al.*, 1989). Subsequently, numerous related peptides and corresponding precursors and genes were identified in several crustaceans (Weidemann *et al.*, 1989; Tensen *et al.*, 1991; de Kleijn *et al.*, 1994, 1995; Ohira *et al.*, 1997; Gu and Chan, 1998; Gu *et al.*, 2000).

Peptides of the CHH family control multiple functions. For example, CHH stimulates glucose and lipid release into the hemolymph, secretion of digestive enzymes from the hepatopancreas, and ion transport in the gill. This peptide also inhibits production of ecdysteroids and methyl farnesoate from endocrine glands (Keller, 1992; Van Herp, 1998; Spanings-Pierrot *et al.*, 2000). Immunohistochemistry revealed that, in several crustaceans, CHH is produced by the eyestalk neuroendocrine system composed of neurosecretory cells in the X-organ and neurohemal sinus gland (Dircksen *et al.*, 1988).

Recent studies showed that CHH immunoreactivity also is produced by a novel endocrine system comprising thousands of endocrine cells in the fore- and hindgut of *Carcinus* (Chung *et al.*, 1999; Webster *et al.*, 2000). Biochemical and molecular evidence confirmed that this gut immunoreactive peptide and its precursor sequence were identical to CHH produced by the eyestalk neurosecretory system (Chung *et al.*, 1999). Massive release of CHH from gut endocrine cells was detected during ecdysis of *Carcinus*, causing water and ion uptake necessary for swelling of the animal and rupture of the epidermal lines, followed by ecdysis of the old cuticle and the subsequent increase in size during postecdysis (Chung *et al.*, 1999). CHH-related peptides likely control water and ion balance in other arthropods as well, as described in the locust (Phillips *et al.*, 1996, 1998).

Ion transport peptide was originally identified in the storage lobe of locust CC and shown to stimulate salt and water reabsorption, and to inhibit acid

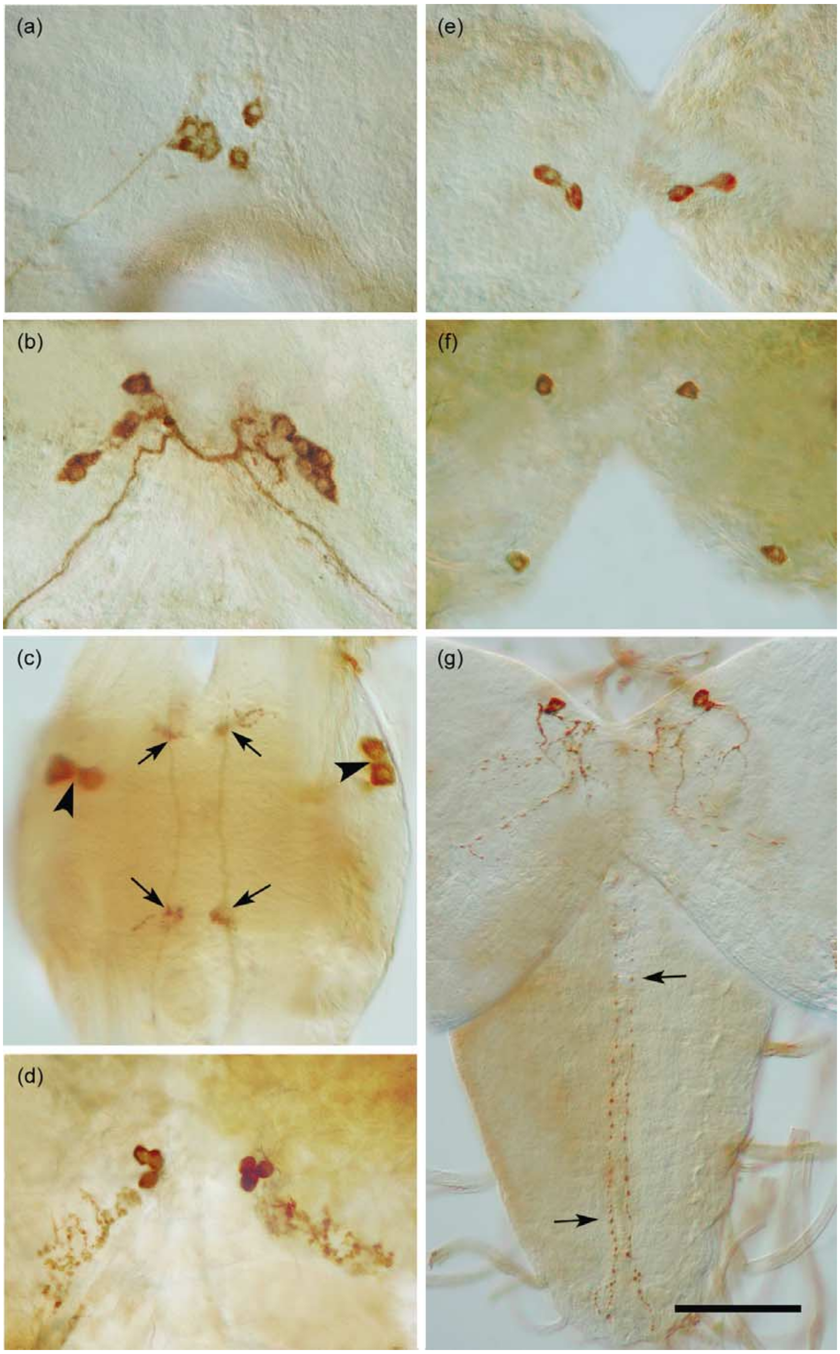

Figure 10 EH-immunoreactivity (EH-IR) in diverse insect species. Hemimetabolous insects usually show a variable number of EH-IR cells in the brain. (a, b) Two brain specimens of the cockroach *Nauphoeta* show EH-IR in a cluster of six (a) and ten (b) ventromedial (VM) cells. (c) VM cells of the cricket *Acheta* project axons throughout the entire nerve cord and make prominent arborizations in each ventral ganglion (AG4, arrows). Two pairs of additional dorsolateral neurons are stained in these ventral ganglia (AG4, arrowheads). (d) Six EH-IR neurons were detected in the brain of the bug *Pyrrhocoris*, but other specimens show 4–9 immunopositive cells. (e) Two pairs of VM cells are stained in the brain of alderfly *Sialis* and (f) antlion *Myrmeleon.* Note that a second pair of VM neurons in *Myrmeleon* is located more posteriorly. (g) Only one pair of EH producing neurons is stained in the dorsomedial brain region of the fruitfly *Drosophila*. These cells arborize in the brain and project two axons along entire ventral nerve cord (arrows). Scale bar = 100 μm in (a–e); 50 μm in (g).

secretion by the hindgut of *Schistocerca gregaria* (Audsley *et al.*, 1992a, 1992b). Western blots with antisera to *Schistocerca* ITP suggest that this peptide is quickly transported from the brain neurosecretory cells into the neurohemal CC–CA. On Western blots, a strongly stained band corresponding to ITP was detected in extracts of two CC–CA, while only a weakly labeled band was visible in extracts of 50 brains (Macins *et al.*, 1999). Using *Schistocerca* ileal bioassays and Western blots, evidence for the presence of ITP was detected in the CC or brain extracts of orthopteroid insects, including several locusts, cricket *A. domestica*, cockroach *Periplaneta americana*, and stick insect *Carausius morosus*. By the same criteria, ITP was not detected in holometabolous insects, such as the moth *Spodoptera litura* and the fly *Neobellieria bullata* (Macins *et al.*, 1999). Nevertheless, precursors encoding peptides related to ITP/CHH have been identified in both hemi- and holometabolous insects such as *Schistocerca, Locusta*, and *Bombyx* (Meredith *et al.*, 1996; Macins *et al.*, 1999; Endo *et al.*, 2000), and gene sequences encoding putative ITPs became generally accessible after publication of the *Drosophila* and *Anopheles* genomes. These precursors and genes encode an amidated 72 amino acid ITP and 1–2 longer free C-terminal ITP-like peptides (Figure 8).

ITP immunoreactivity and mRNA encoding the peptide occur in the CNS of moths. *In situ* hybridization with anti-sense riboprobes detected ITP mRNA in 5–6 pairs of large neurons in the *Bombyx* brain (Endo *et al.*, 2000). Immunohistochemical staining with CHH and ITP antisera (Figure 9c; Spalovská-Valachová and Zitnan, unpublished data) showed that these neurons are ipsilateral neurosecretory cells (type Ia$_2$). Smaller paired neurons were also stained in each ventral ganglion of *Schistocerca* and *Manduca* (Dircksen and Heyn, 1998; Spalovska-Valachova and Zitnan, unpublished data).

At the present time, definitive roles for ITP/CHH-like peptides in insect ecdysis are not well understood. But based on analogy with gut CHH in crustaceans and the demonstrated role of ITP in gut ion transport in locusts, it is speculated that blood-borne ITP may control functions associated with water reabsorption or air inflation, which are necessary preparatory steps for shedding of the old cuticle.

3.1.2.5. Crustacean Cardioactive Peptide

A neuropeptide with heart stimulatory activity, crustacean cardioactive peptide (CCAP), was originally identified from the CNS of crab *Carcinus maenas* (Stangier *et al.*, 1987). Later, identical neuropeptides were isolated from the CNS of the various insects including locust *L. migratoria*, beetle *T. molitor*, and moths *Spodoptera eridania* and *M. sexta* (Figure 11; Stangier *et al.*, 1989; Cheung *et al.*, 1992; Furuya *et al.*, 1993; Lehman *et al.*, 1993). The gene encoding a single copy of CCAP was identified in *Manduca* and *Drosophila* (Loi *et al.*, 2001).

CCAP	PFCNAFTGCamide	
Locusta MIP	AWQDLNAGWamide	
Manduca MIP1	AWQDLNSAWamide	100%
Manduca MIP2	GWQDLNSAWamide	20%
Manduca MIP3	APEKWAAFHGSWamide	20%
Manduca MIP4	GWNDMSSAWamide	20%
Manduca MIP5	GWQDMSSAWamide	50%
Manduca MIP6	AWSALHGAWamide	20%
Drosophila MIP1	AWQSLQSSWamide	
Drosophila MIP2	AWKSMNVAWamide	
Drosophila MIP3	EAQGWNKFRGAWamide	
Drosophila MIP4	EPTWNNLKGMWamide	
Drosophila MIP5	DQWQKLHGGWamide	

Figure 11 Amino acid sequences of CCAP and MIPs from different insect species. Green/turquoise represent sequence identity, yellow sequence similarity.

Immunohistochemical studies with antisera to CCAP revealed a conserved pattern of paired lateral neurons in subesophageal, thoracic, and abdominal ganglia (AG1–7) in *Ctenolepisma, Thermobia, Locusta, Gryllus, Tenebrio, Aedes, Drosophila*, and *Calliphora* (Figures 12 and 13; Breidbach and Dircksen, 1991; Dircksen *et al.*, 1991; Jahn *et al.*, 1991; Helle *et al.*, 1995; Ewer and Truman, 1996; Kostron *et al.*, 1996). These paired neurons were identified in *Manduca* as neurosecretory cells 27 (or NS-L$_1$) and interneurons 704 (IN-704) (Taghert and Truman, 1982a; Sandstrom and Weeks, 1991; Davis *et al.*, 1993; Ewer *et al.*, 1994). Homologs of Cell 27 in *Gryllus* and *Periplaneta* were described as lateral white (LW) cells (Adams and O'Shea, 1981; O'Shea and Adams, 1981), while homologs of 27 and 704 were named type I and II neurons in *Locusta* (Dircksen *et al.*, 1991; Davis *et al.*, 2003). However, for the sake of clarity, they are referred to as cells 27 and IN-704 here.

Examples of CCAP-IR neurons in various insects including silverfish *Lepisma saccharina*, cockroach *Periplaneta*, locust *Locusta*, cricket *A. domestica*, walking stick *Caraussius morosus*, bug *Pyrrhocoris apterus*, alderfly *Sialis* sp., antlion *Myrmeleon* sp., mealworm beetle *T. molitor*, and silkworm *B. mori* are shown in Figures 12 and 13. These insects show CCAP immunoreactivity (CCAP-IR) in a neuronal network closely resembling cells 27 and 704 (27/704 network) described in ventral ganglia of *Manduca* (Sandstrom and Weeks, 1991; Davis *et al.*, 1993; Ewer *et al.*, 1994; Ewer and Truman, 1996). However, the number and spatial expression of CCAP

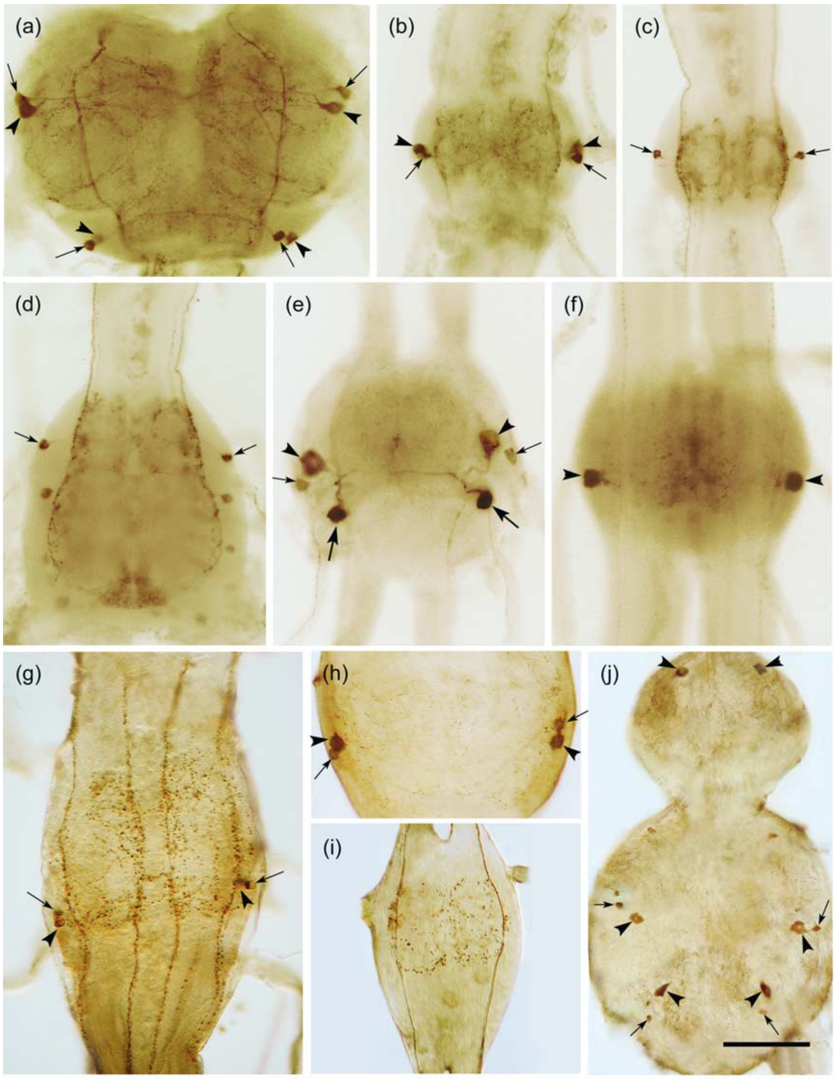

Figure 12 Variability of CCAP-IR in the CNS of hemimetabolous insects. All insects show CCAP-IR in putative homologs of neurosecretory cells 27 (arrowheads) and interneurons 704 (IN-704; small arrows). (a–d) In *Periplaneta americana* both cell types are stained in the fused TG3-AG1 (a) and anterior unfused AG4 (b), while posterior AG5 (c) and TAG (d) lack cells 27 and show only staining in IN-704 and several other small cells. (e) In addition to cells 27/704, *Locusta migratoria* shows a very strong CCAP-IR in a pair of large neurosecretory cells in AG5 (large arrows). (f) CCAP-IR in *Acheta* is restricted to a pair of cells 27 in AG5. (g) One pair of 27/704 homologs is stained in AG4 of *Lepisma*. (h, i) In *Carausius* cells 27/704 are detected in the TG2 (h), but no cell bodies are stained in AG5 (i). (j) Similarly, TG1-3 of *Pyrrhocoris* show CCAP-IR in putative 27/704 cells, but no immunopositive cells are found in the fused abdominal ganglion. Immunoreactive axons in AG of the two latter species probably originate from 27/704 cells in the SG and TG1-3. Scale bar = 100 μm.

producing cells in different ganglia is quite variable (Figures 12 and 13). Two pairs of putative cells 27 and 704 are usually stained in the SG of all hemimetabolous insects examined (Dircksen *et al.*, 1991; Ewer and Truman, 1996), while only one pair of these neurons is detected in TG1–3 (Figure 12a and h). One pair of 27/704 homologs is also stained in AG1–7 of *Lepisma* (Figure 12g), but other insects show much more variable expression of CCAP-IR in abdominal ganglia. For example, in *Periplaneta* CCAP-IR is detected in paired cells 27 and 704 of AG1–4, while cells 27 appear to be missing in AG5–7, so only paired IN-704 are stained in these posterior ganglia (Figure 12a–d). *Locusta* shows CCAP-IR in 27/704 cells in all AG1–7, plus a very strong staining is detected in another pair of large neurosecretory cells in AG1–6 (Figure 8e; Dircksen *et al.*, 1991). These cells probably also produce bursicon and show cGMP elevation during ecdysis (Truman *et al.*, 1996; see Sections 3.1.1.3 and 3.1.6.2). CCAP-IR in *Acheta* is restricted to a pair of cells 27 in each AG1–7; the dragonfly *Sympetrum* sp. shows a very

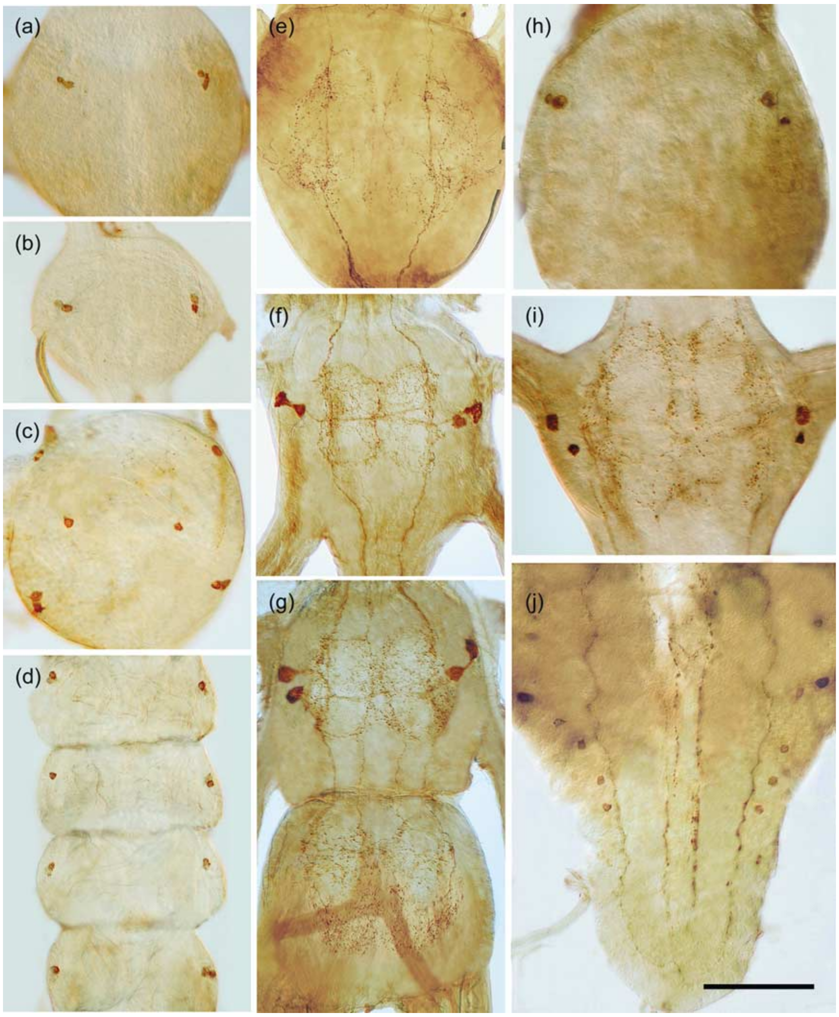

Figure 13 CCAP-IR in the ventral nerve cord of holometabolous larvae. A network of CCAP-IR neurons 27/704 is more conserved in holometabolous insects. (a, b) One pair of putative cells 27 and IN-704 is detected in each TG2 (a) and AG4 (b) in *Sialis.* (c, d) A similar distribution of CCAP-IR cells 27/704 is detected in the TG2 (c) and AG3-6 (d) of *Myrmeleon*, but some additional neurons are stained in the TG2. (e–g) In *Bombyx* larvae, cells 27/704 show strong immunoreactivity in AG4 (f) and AG7 (g), but homologous cells are not stained in TG2 (e). (h, i) A pair of cells 27/704 are detected in the TG2 (h) and AG7 (i) of *Tenebrio.* (j) *Drosophila* shows CCAP-IR in one pair of lateral cells probably homologous with cell 27 in each thoracic and first six abdominal neuromeres. Scale bar = 100 μm in (a–d); 200 μm in (e–i); 50 μm in (j).

similar staining pattern (not shown). By contrast, no cell bodies are stained in AG1–7 of *Caraussius* or fused abdominal ganglion of *Pyrrhocoris*. Strongly stained axons in abdominal ganglia of these two species probably originate from cells 27/704 detected in the SG and TG1–3 (Figure 12h–j).

A network of CCAP-producing neurons appears to be more conserved in holometabolous insects. Two pairs of putative cells 27 and IN-704 in the SG and one pair of these cells in each TG1–3 and AG1–7 show CCAP-IR in *Sialis* (Figure 13a and b), *Myrmeleon* (Figure 13c and d), *Tenebrio* (Figure 13h and i), and *Aedes* (Ewer and Truman, 1996). *Bombyx* larvae express similar staining in 27/704 cells of AG1–7 as described in other holometabolous species, but these cells lack CCAP-IR in the SG and TG1–3 (Figure 13e–g). *Drosophila* shows CCAP-IR in 3–4 pairs of lateral cells (probably homologs of cell 27) in the SG region and three pairs in TG1–3, while one pair of cells is usually stained in each of the first six abdominal neuromeres (Figure 13j; Ewer and Truman, 1996; Park *et al*., 2003b).

Using immunohistochemistry and *in situ* hybridization techniques, developmental expression of CCAP and its mRNA precursor was described in *Manduca* (Loi *et al*., 2001; Davis *et al*., 2003). In larval stages, strong CCAP-immunoreactivity is only present in one pair of cells 27/704 in each AG1–7

(Davis *et al*., 2003). Curiously, thoracic homologs of 27/704 cells do not appear to produce CCAP in *Manduca* larvae, instead these cells express IgG-like protein (Klukas *et al*., 1996). CCAP staining appears in 27/704 neurons in the pupal stage, but vanishes after adult emergence (Davis *et al*., 1993). CCAP-IR is also detected in three pairs of brain interneurons and several neurons in abdominal ganglia (e.g., a pair of motoneurons MN1, two medial neurosecretory cells NC4, and two ventral unpaired medial (VUM) neurons, as well as in the peripheral segmental neurons L1 (Davis *et al*., 2003). A very similar pattern of cell types was also shown by *in situ* hybridizations with the CCAP probe (Loi *et al*., 2001). These data suggest that most or probably all CCAP-IR cells produce genuine CCAP. Both immunohistochemistry and *in situ* hybridization techniques showed that different cell types express CCAP at specific developmental stages (Davis *et al*., 1993; Loi *et al*., 2001).

Neurons 27/704 in *Manduca* and their homologs in other diverse insects produce cGMP during each ecdysis (Ewer *et al*., 1994; Ewer and Truman, 1996), which is associated with increased excitability and CCAP release from these cells. The central release of CCAP from a network of 704 neurons in *Manduca* has been implicated as a crucial signal for the initiation and maintenance of the ecdysis motor program residing in abdominal ganglia (Gammie and Truman, 1997a; Zitnan and Adams, 2000; see Section 3.1.6.1.3). Other *in vitro* bioassays indicate that peripherally released CCAP acts as a neurohormone to stimulate heart, oviduct, and hindgut contractions in *Locusta* and *Manduca* (Cheung *et al*., 1992; Donini *et al*., 2001; Donini *et al*., 2002). CCAP in cells 27 is apparently colocalized with bursicon in *Periplaneta, Gryllus, Manduca*, and probably other insects (Kostron *et al*., 1996; Honegger *et al*., 2002). These peptides are very likely coreleased following ecdysis to control postecdysis processes; CCAP increases heart beat and blood pressure for cuticle expansion, while bursicon controls sclerotization and tanning of expanded new cuticle (see Section 3.1.6.6.2).

Using immunohistochemistry and radioimmunoassays, CCAP was detected in the CNS of several crustaceans, spiders (arachnids), and an opilionid (Dircksen and Keller, 1988; Stangier *et al*., 1988; Breidbach *et al*., 1995; reviews: Dircksen, 1994, 1998). High levels of CCAP were also detected in the hemolymph during ecdysis of decapod crustaceans, *Carcinus maenas* and *Orconectes limosus* (Phlippen *et al*., 2000). The identical structure and widespread occurrence of CCAP in a network of similar cells in various arthropods indicates a conserved function for this peptide. Experimental data provide increasing evidence that CCAP plays an important role in regulation of insect and crustacean ecdysis. However, targeted ablation of CCAP expressing neurons in *Drosophila* did not dramatically affect larval and adult ecdyses, but most animals showed severe defects during pupation and died in the pupal stage (Park *et al*., 2003b; for more details, see Section 3.1.6.3.5). The defect appears to result from an inability of the circulatory system to generate blood pressure sufficient to produce head eversion, which is necessary for successful pupation.

3.1.2.6. Myoinhibiting (Myoinhibitory) Peptides

This family of closely related neuropeptides with gut myoinhibitory activity has been identified in widely divergent insect species using various types of bioassays. They have been variously referred to as myoinhibiting peptides (MIPs) or allatostatin B peptides. The first of these was identified in cephalic ganglia of *L. migratoria*, where it was found to inhibit rhythmic contractions of the isolated hindgut and oviduct of this species and of the hindgut of the cockroach *Leucophaea maderae* (Schoofs *et al*., 1991). Another MIP inhibiting visceral muscle contractions was isolated from the CC–CA extracts of the cockroach *P. americana* (Predel, 2001). Several peptides closely related to MIPs subsequently were isolated from brains of *Gryllus bimaculatus* and *Carausius morosus*. Because they suppress juvenile hormone (JH) biosynthesis by the CA of adult crickets *in vitro*, they were named allatostatins type B. However, they failed to suppress JH production in *Carausius* (Lorenz *et al*., 1995; Lorenz *et al*., 2000). Since these peptides originally were named on the basis of gut inhibitory activity, these are referred to as MIP peptides.

In holometabolous insects, six similar MIP neuropeptides (Mas-MIP I–VI) were identified from extracts of adult *M. sexta* abdominal ganglia. The relative quantities of these peptides were conspicuously different, with ratios of 5 (MIP I):2.5 (MIP IV):1 (MIPs II, III, IV, and VI). Each peptide suppressed spontaneous contractions of the isolated hindgut (ileum) of adult *Manduca* (Blackburn *et al*., 1995, 2001). Recently, a “prothoracicostatic hormone” (PSTH) identical to Mas-MIP1 was isolated from larval brains of *B. mori* (see **Chapter 3.2**). This peptide inhibits production of ecdysteroids from prothoracic glands *in vitro* (Hua *et al*., 1999). The cDNA precursor for *Bombyx* MIP (PSTH) encodes 13 copies of seven closely related peptides (GenBank

Accession No. AB073553). Interestingly, the precursor contains five copies of MIP I (PSTH 1), two copies of MIP II and MIP V, and single copies of the other MIPs. This stoichiometry likely explains the different amounts of MIPs found in *Manduca* CNS extracts (Blackburn *et al*., 2001). Finally, a *Drosophila* cDNA precursor encoding five deduced peptides closely related to MIPs has been described (Williamson *et al*., 2001). Primary structures of MIPs from various insect species are shown in **Figure 11**.

Immunohistochemical staining has been used to detect neurons producing MIPs from several species in the cephalic ganglia of cockroaches *Leucophaea maderae* and *P. americana*, moth *Mamestra brassicae*, fly *Neobellieria bullata*, and in the entire CNS of *L. migratoria*. MIP immunoreactivity was detected in the brain medial neurosecretory cells projecting to the CC–CA complex and in a few smaller neurons in the brain and ventral nerve cord (Veelaert *et al*., 1995; Schoofs *et al*., 1996; Predel, 2001).

Using *in situ* hybridization with antisense riboprobes, MIP expression was detected in the CNS neurons of *Drosophila*. Four pairs of medial cells were revealed in the protocerebrum and a pair of lateral neurons was stained in each abdominal neuromere (Williamson *et al*., 2001). Paired neurons in the fused abdominal ganglion are probably homologs of the IN-704, which show MIP immunoreactivity in abdominal ganglia (AG1–7) of *Manduca* and *Bombyx* (Davis *et al*., 2003). Detection of MIPs in IN-704 (**Figure 9d**) is of particular interest, since they also express CCAP (Davis *et al*., 1993; Loi *et al*., 2001) an important central signal for the ecdysis motor program. Release of MIPs within CNS ganglia is indicated by decreased staining in the IN-704 and nerve arborizations after ecdysis (Davis *et al*., 2003). The role of MIPs at ecdysis is described in Section 3.1.6.1.3. In larval stages of both moths, MIP-immunoreactivity was also located in small neurons in the brain, as well as in large neurons innervating the hindgut from the terminal abdominal ganglion (TAG; Davis *et al*., 2003). None of these neurons appear to release MIPs into the hemolymph in larvae. However, adult brains show MIP staining in two pairs of the medial neurosecretory cells, which are known to produce diuretic hormone and allatostatins (Davis *et al*., 2003).

The likely source of hemolymph-borne MIPs in larvae is a pair of epiproctodeal glands, each composed of two large neurosecretory cells. Both glands are located on lateral sides of the hindgut and are part of the proctodeal nervous system (Reinecke *et al*., 1978; Zitnan *et al*., 1995a; Davis *et al*., 2003). Interestingly, gradual accumulation followed by a rapid decrease of MIP-IR was observed during the 4th larval instar. A marked decrease of MIP-IR coincides with the decline of ecdysteroid titer at the end of the instar. This suggests that MIPs may initiate the decline of ecdysteroids from prothoracic glands at that time. Indeed, MIP I (PTSH) inhibits ecdysteroid production from prothoracic glands of *B. mori in vitro* (Hua *et al*., 1999). Another possible source of circulating MIPs may come from a subset of midgut (gastric) endocrine cells, which show immunohistochemical staining in *Manduca* and *Bombyx* (Spalovská-Valachova and Zitnan, unpublished data). Expression of MIPs in these endocrine cells was confirmed by *in situ* hybridization in the *Drosophila* midgut (Williamson *et al*., 2001).

3.1.2.7. Corazonin

Corazonin was originally isolated as a potent cardioaccelerator from the CC of the cockroach *P. americana* (**Figure 14**), (Veenstra, 1989). The identical peptide was later found in other cockroaches, cricket and two moths, but surprisingly the peptide exhibited no cardioacceleratory activity in these insects (Veenstra, 1991; Hua *et al*., 2000; Predel, 2001). Another form of corazonin with a substitution at position 7 (His^{7}-corazonin) was identified

Corazonin	pQTFQYSRGWTNamide
His-corazonin	pQTFQYSHGWTNamide
Drosophila, Neobellieria	TDVDHVFLRFamide
Schistocerca, Locusta	PDVDHVFLRFamide
Locusta	ADVGHVFLRFamide
Leucophea	pQDVDHVFLRFamide
Manduca F10	pQDVVHSFLRFamide
Manduca F24	VRDYPQLLDSGMKRQDVVHSFLRFamide
Manduca F39	YAEAAGEQVPEYQALVRDYPQLLDSGMKRQDVVHSFLRFamide
Manduca F7D	DPSFLRFamide
Manduca F7G	GNSFLRFamide

Figure 14 Amino acid sequences of corazonins and FLRFamide-related peptides. Green represents sequence identity, yellow sequence similarity.

in grasshoppers, *S. americana*, *S. gregaria*, *L. migratoria*, and stick insect *C. morosus* (**Figure 14**) (Veenstra, 1991; Predel *et al*., 1999; Tawfik *et al*., 1999). The gene and cDNA encoding corazonin were described in *D. melanogaster* and in the wax moth *Galleria mellonella*, respectively. Preprocorazonin of both species contains corazonin and a longer, nonamidated peptide, corazonin precursor-related peptide of unknown function (Veenstra, 1994; Hansen *et al*., 2001).

Antisera to corazonin were used to identify corazonin producing neurons in the CNS of representatives from eight diverse insect orders (Veenstra and Davis, 1993; Cantera *et al*., 1994; Roller *et al*., 2003). In all insects except the beetle, corazonin immunoreactivity occurs in a cluster of prominent ipsilateral-projecting neurosecretory cells in the protocerebrum and in smaller cells, mostly interneurons, in the ventral nerve cord (Roller *et al*., 2003). Northern blots and *in situ* hybridizations confirmed expression of the corazonin gene in four pairs of brain lateral neurosecretory cells in *G. mellonella*, while cells in the ventral ganglia, fat body, gut, and several other organs failed to show expression of corazonin mRNA (Hansen *et al*., 2001). The brain lateral neurosecretory cells producing corazonin have been identified as Ia_1 cells originally described in *Manduca* (**Figure 9a**; Copenhaver and Truman, 1986b; Homberg *et al*., 1991; Zitnan *et al*., 1995b). Expression of corazonin in these lateral cells of moths attracted the attention of several research groups, since these cells appear to be involved in the regulation of circadian rhythms (Sauman and Reppert, 1996). Indeed, the circadian clock protein Period (Per) is colocalized with corazonin in Ia_1 cells of *Manduca* as detected by the double staining with a monoclonal antibody to Per and rabbit antiserum to corazonin (Wise *et al*., 2002). These cells appear to be involved in the regulation of circadian rhythms in the silkmoth *Antheraea pernyi* (Sauman and Reppert, 1996). *Manduca* larvae with surgically ablated type Ia_1 cells are not able to enter diapause after pupation, indicating that some of these cells may control photoperiod-induced pupal diapause (Shiga *et al*., 2003).

His^7 corazonin was isolated from the CC of two locusts as a dark pigment inducing agent controlling phase polymorphism (melanization) in an albino mutant and in normal nymphs of *L. migratoria* (Tanaka and Pener, 1994; Tawfik *et al*., 1999). But while corazonin also induces cuticle melanization in other locust species, this effect does not appear to extend beyond this group (Tanaka, 2000). Implantation of CNS ganglia, or injection of their extracts from representatives of 13 insect orders induced cuticle melanization in the albino locust, but failed to evoke melanization in donor species (Tanaka, 2000; Roller *et al*., 2003). These data indicate that most insects produce corazonin, but its role in cuticle melanization is specific for locusts (Tanaka, 2001). Injection of corazonin also prolonged the spinning period at the end of the 5th larval instar and delayed adult development in pupae of *B. mori* (Tanaka *et al*., 2002), but the functional significance of these effects is not clear.

The identification of corazonin in many different insect groups, together with its localization by immunohistochemical staining and bioassays suggest that corazonin is a highly conserved and widespread insect neuropeptide, but that its physiological function is still unclear. Recent experiments suggest that corazonin induces the release of PETH and ETH from Inka cells of moths to initiate the ecdysis behavioral sequence (Kim *et al*., 2004; see Section 3.1.5.2).

3.1.2.8. FLRFamide-Related Peptides

Since the discovery of the first tetrapeptide FMRFamide (Phe-Met-Arg-Phe-amide) in the mollusk *Macrocallista nimbosa* (Price and Greenberg, 1977), a large number of FMRFamide-related peptides (FaRPs) have been identified in various invertebrates and vertebrates (Gäde, 1997). These peptides are encoded by multiple genes and expressed in various types of cells. For example, at least four *Drosophila* genes encode N-terminally extended –RFamides, including FMRFamides, myosuppressins, sulfakinins, and neuropeptide F (NPF). These peptides are produced by specific cells of the CNS and gut (Nambu *et al*., 1988; Schneider and Taghert, 1988; O'Brien *et al*., 1991; Schneider *et al*., 1991; Nichols *et al*., 1995, 1997; Nichols and Lim, 1996; Benveniste and Taghert, 1999; Brown *et al*., 1999); for recent reviews see: Nichols *et al*., 2002; Nichols, 2003). Differential expression and effects of these peptides indicate their involvement as neuromodulators and neurotransmitters in distinct functions.

Recent studies suggest participation of *Manduca* FLRFamides in the regulation of ecdysis, and consequently our discussion will be limited to these. Quantitative analysis of three FLRFamides (F7G, F7D, and F10; **Figure 14**) originally isolated from the *Manduca* CNS (Kingan *et al*., 1990, 1996) showed that larval, pupal, and adult ecdyses are associated with decline of these peptides in ventral ganglia (Miao *et al*., 1998). Since FLRFamide-like staining was found in fine fibers innervating skeletal and visceral muscles, these authors proposed that release of these peptides could modulate muscle

performance during the ecdysis behavioral sequence. Consistent with this hypothesis, elevated levels of F7D and F10 were detected in the hemolymph 10 min after adult emergence (Kingan *et al.*, 1996). The release of F10 at ecdysis also is suggested by the considerable reduction of its precursor mRNA levels in the ventral nerve cord following each larval, pupal, and adult ecdysis (Lu *et al.*, 2002). Independent experiments suggest that F10 from the nervous system and its extended isoforms, F24 and F39, isolated from the midgut (Kingan *et al.*, 1990; Kingan *et al.*, 1997b) induce the ecdysis sequence when injected into pharate 4th or 5th instar *Manduca* larvae (Spalovská-Valachová, Kingan, Adams, Zitnan, unpublished data; see Section 3.1.5.2).

Decapeptides closely related to F10 have been isolated from the CNS of cockroaches, locusts, moths, and flies (Gäde, 1997). The gene or cDNA precursors encode only a single copy of this peptide in the cockroach *D. punctata*, fruitfly *D. melanogaster*, and moths *P. unipuncta* and *M. sexta* (Donly *et al.*, 1996; Bendena *et al.*, 1997; Vanden Broeck, 2001; Lu *et al.*, 2002). Other FaRPs therefore are encoded by different genes, which have been previously identified in *Drosophila* (Nichols *et al.*, 2002). Antisera to FMRFamide, which cross-react with all FaRPs, indicated a widespread distribution of these peptides in the CNS, enteric (stomatogastric) nervous system and midgut (gastric) endocrine cells of many insects (Copenhaver and Taghert, 1989; Homberg *et al.*, 1990; Zitnan *et al.*, 1995a; Sehnal and Zitnan, 1996).

Using *in situ* hybridization, reaction with F10 riboprobes occurs in a subset of FMRFamide-immunopositive neurons in the CNS (Lu *et al.*, 2002). Notably, this includes neurosecretory cells known as type Ia_1, IIa_5, and III (Copenhaver and Truman, 1986a; Zitnan *et al.*, 1995b). The presence of F10 in Ia_1 cells is of special interest, since double immunohistochemical staining indicates that F10 is colocalized with corazonin (**Figure 9a** and **b**) and the clock protein Per in these neurons (Wise *et al.*, 2002; see **Chapter 4.11**). Circadian expression of Per and Timeless (Tim) proteins in Ia_1 cell homologs in the moth *Antheraea pernyi* have been implicated in timing of the gated larval hatching from eggs (Sauman *et al.*, 1996), as well as adult emergence and daily activity of this moth (Sauman and Reppert, 1996; see **Chapter 4.11**). No daily rhythm in Per expression has been detected in *Manduca* (Wise *et al.*, 2002), but it is possible that Per may control the release of F10 and corazonin to initiate gated ecdysis or eclosion observed in several moths and butterflies (Truman, 1972, 1974; Zitnan, unpublished data).

Differential processing of the *Manduca* F10 protein precursor is indicated by the presence of F10 in the CNS and anterior/posterior midgut innervated by enteric and central neurons, while most F24 and F39 immunoreactivity was isolated from the middle/posterior midgut containing hundreds of immunopositive endocrine cells (Zitnan *et al.*, 1995a; Kingan *et al.*, 1997b). These results suggest that F24 and F39 are completely processed to F10 in neurons of the CNS and enteric plexus, whereas midgut endocrine cells produce the partially processed isoforms F24 and F39. However, using *in situ* hybridization, expression of mRNA encoding the precursor for F10, F24, and F39 was detected only in midgut endocrine cells, while no such F10 transcript was found in neurons of the frontal ganglion and enteric plexus of *Manduca* (Lu *et al.*, 2002). Similarly, expression of mRNA encoding F10–39 homologs was only observed in CNS neurons and midgut endocrine cells of the adult moth *P. unipuncta* (Lee *et al.*, 2002). These data suggest that FMRFamide-IR neurons in the frontal ganglion and enteric plexus produce peptide(s) different from F10. In contrast, expression of mRNA encoding the cockroach homolog of F10 (leucomyosuppressin) was observed in both central and stomatogastric (enteric) neurons as well as in endocrine cells scattered in the anterior midgut epithelium (Fuse *et al.*, 1998). In *Drosophila*, a discrete set of neurons in the CNS and two cells attached to the hindgut were also stained with a specific antibody to the F10 homolog, dromyosuppressin (McCormick and Nichols, 1993).

Closely related FLRFamide decapeptides generally are referred to as myosuppressins since they exhibit inhibitory activity on visceral muscles using *in vitro* bioassays with crop, hindgut, oviduct or heart in several insect species (Robb and Evans, 1990; Fujisawa *et al.*, 1993; Lange *et al.*, 1994; Fuse and Orchard, 1998; Duttlinger *et al.*, 2002). However, the same peptides elicit contractions of skeletal muscles (Kingan *et al.*, 1990; Robb and Evans, 1990; Lange and Cheung, 1999) and also stimulate secretion of digestive enzymes (alpha amylase and invertase) from the gut of the scallop *Pecten maximus*, cockroach *D. punctata*, and beetle *Rhynchophorus ferrugineus* (Nachman *et al.*, 1997; Fuse and Orchard, 1998). Other shorter FLRFamides or FIRFamides derived from different genes show effects opposite to those of the myosuppressins. For example, *Locust* GQERNFLRFamide, AXXRNFIRFamide, and AFIRFamide and *Manduca* heptapeptides F7G and F7D exhibit stimulatory effects on visceral muscles in the same or similar bioassays as described above (Lange *et al.*, 1994; Kingan *et al.*,

1996; Miao *et al.*, 1998). In addition, F7G and F7D were shown to inhibit ion transport through the midgut epithelium in *Manduca* (Lee *et al.*, 1998). Therefore, it is clear that FLRFamides can be both excitatory and inhibitory, depending on the cellular context.

Despite all of this information on the activities of FLRFamides, their authentic physiological functions are not well understood. The authors speculate that inhibitory actions of F10 may suppress functions not related to ecdysis, while stimulatory actions on skeletal muscles and on Inka cell secretion control specific behaviors associated with shedding of the old cuticle. Identification of specific receptors for FaRPs, determination of spatial and temporal expression patterns of these receptors and their specific ligands along with physiological experiments should help to understand the roles of these structurally related, but functionally diverse peptides.

3.1.3. Peptide Receptors in Ecdysis

3.1.3.1. Introduction

Classical approaches to receptor identification have changed dramatically in recent years with publication of entire organismal genomes. Just 20 years ago, receptor identification was accomplished strictly through biochemical approaches, and could only succeed in instances where tissue receptor density was very high. In addition, highly specific ligands often were needed to guide isolation of receptor proteins for N-terminal sequencing. The most famous example is that of the nicotinic acetylcholine receptor, present at 2% of total protein in *Torpedo* electroplax, a modified muscle used to electrocute prey. The snake toxins α-bungarotoxin and cobra toxin were useful in characterization of the receptor, from which N-terminal sequence information was obtained (Raftery *et al.*, 1980). This provided the necessary information for design of oligonucleotides subsequently employed as probes of cDNA libraries. In this manner, the first fully sequenced nicotinic receptor was elucidated (Noda *et al.*, 1983) (see **Chapter 5.3**). Similar approaches quickly led to complete sequences for other members of the ligand-gated channel superfamily as well as ion channels such as the sodium channel, L-type calcium channel, and β-adrenergic receptor, to name a few (Numa, 1989; Betz, 1990).

The identification of G protein-coupled receptors (GPCRs) for amines and peptides began with identification of the β-adrenergic receptor, a 7-transmembrane GPCR related to rhodopsin (Dixon *et al.*, 1986; Lefkowitz and Caron, 1988) (see **Chapter 5.5**). These representative templates then guided identification of new members of each class through construction of degenerate oligonucleotide primers and more recently through employment of the polymerase chain reaction (PCR). Among the first peptide GPCRs to be identified in insects were the tachykinin/neuropeptide Y/galanin-like receptors (Li *et al.*, 1991; Li *et al.*, 1992; Monnier *et al.*, 1992) and the *Manduca* diuretic hormone receptor, elucidated through expression cloning (Reagan, 1994, 1996).

Access to the *Drosophila* and human genomes (Adams *et al.*, 2000) has greatly facilitated the identification of putative peptide hormone receptors based on homology to mammalian hormone GPCRs (Brody and Cravchik, 2000; Hewes and Taghert, 2001; Vanden Broeck, 2001). Entire sets of receptor genes in each class can be recognized through sequence similarities and sorted into categories, and such insights are helping to direct the next era of functional analysis. Through genome analysis, the process of using an "orphan" ligand to probe for its unknown receptor has been reversed. A plethora of orphan receptors are now being cloned and heterologously expressed in oocytes or cell lines, where they function as sensors for libraries of ligands. In some instances, this process has been referred to as "reverse physiology," in which the expressed receptor is used to isolate unknown ligands from tissue extracts (Meunier *et al.*, 1995; Reinscheid *et al.*, 1995). This approach has been taken to isolate some of the first insect GPCR-type receptors for neuropeptides (Birgul *et al.*, 1999) (see **Chapter 5.5**). Thus, the data provided via public access to the *Drosophila*, nematode, and human genome projects combined with heterologous expression and reverse physiology approaches have greatly accelerated elucidation of ligand–receptor relationships.

Hewes and Taghert delineated 44 genes likely to encode peptide receptors in *Drosophila* (Hewes and Taghert, 2001). Strategies for "de-orphaning" these receptors have varied, with some laboratories taking a shotgun approach, randomly cloning and heterologously expressing receptors for screening of ligand libraries. These approaches presume that the highest affinity ligand will likely be the authentic physiological transmitter or hormone for that receptor, and in most cases this should turn out to be true. Others have taken a more evolutionary approach toward predicting likely receptors for particular ligands based on a theory of ligand–receptor coevolution. By using multiple databases, known ligand–receptor pairs can be used as guides for predicting the ligands of orphan receptors in other organisms.

The following sections summarize recent progress in the identification of hormone receptors likely to be involved in the ecdysis behavioral sequence, including those for ETH, CCAP, corazonin, FaRPs, and MIPs.

3.1.3.2. Discovery of the First Ecdysis-Related Receptors

Taking a bioinformatics approach to receptor identification, Park *et al*. recently identified a number of GPCRs, including receptors for CCAP and corazonin, that are likely to participate in ecdysis signaling (Park *et al*., 2002b). Ironically, these receptors were discovered in a screen for ETH receptors. A survey of the human genome was performed for peptide ligands having ETH-like -PRXamide [PRXG(KR)] C-terminal amino acid motifs. This sequence motif is characteristic of ETH and a number of other insect peptides, including pheromone biosynthesis activating neuropeptide (PBAN), cardioacceleratory peptides (CAPs), and diapause hormone. Several human peptides share the same motif, namely neuromedin U-25, vasopressin, and pancreatic polypeptide. Further analysis led to the conclusion that genes encoding neuromedin U-25 and vasopressin were most likely to have coevolved on the basis of their C-terminal amino acid sequences. Since corresponding receptors for these peptides already had been identified in the human system, it was possible to group a small number of *Drosophila* orphan GPCRs with neuromedin and vasopressin receptors by sequence homology. These receptor groupings led to a hypothesis that seven *Drosophila* GPCRs closely related to either vasopressin (CG6111, CG10698, CG11325) or neuromedin U (CG8795, CG8784, CG14575, CG9918) were likely candidates for -PRXamide ligand receptors (Figure 15).

Cloning and expression of the *Drosophila* receptors in *Xenopus* oocytes revealed that those in the neuromedin group are highly sensitive to -PRXamide peptides, including PBAN-like *hug* peptides (CG8795), CAP peptides (CG14575), and to a lesser extent, ETHs from both *Drosophila* and *Manduca*. In contrast, *Drosophila* GPCRs in the vasopressin group did not respond to -PRXamide peptides, but instead showed sensitivity to CCAP (CG6111), corazonin (CG10698), and adipokinetic hormone (AKH; CG11325) (Staubli *et al*., 2002). The involvement of CCAP receptors in ecdysis has been suggested by the ability of its ligand CCAP to elicit ecdysis motor patterns in isolated nerve cords of *Manduca* (Gammie and Truman, 1997a, 1999; Zitnan and Adams, 2000). A role for corazonin in ecdysis initiation has been shown recently in *Manduca* (Kim *et al*., 2004). Characteristics of CCAP and corazonin receptors are covered in more detail in the following sections.

Despite the fact that CG8795 responded to both *Drosophila* ETH1, it was considered unlikely to be the authentic ETH receptor. This conclusion was based on the relatively higher sensitivity of this receptor to PBAN-like *hug* peptides, and the fact that sensitivity to ETH was too low to be of physiological significance, based on blood levels of ETHs previously documented (Zitnan *et al*., 1999). Indeed, a recent account has demonstrated that the CG8795 ortholog in *Helicoverpa zea* is a likely

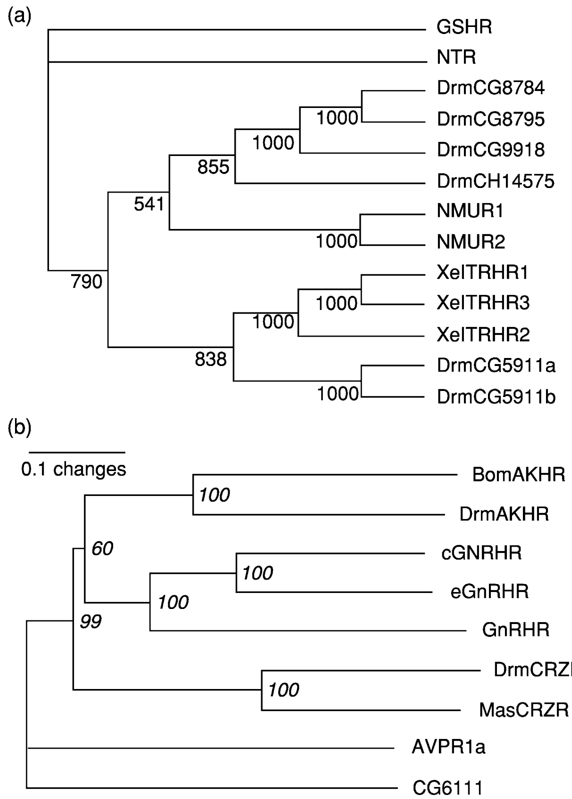

Figure 15 Evolutionary relationships of some ecdysis-related receptors. (a) Two *Drosophila* ETH receptors DrmCG5911a and DrmCG5911b are splice variants of the gene *CG5911*. These putative transcripts are grouped with thyrotropin-releasing hormone receptors (TRHR) in a distance tree with a bootstrapping value of 83.8%. (Data from Park, Y., Kim, Y.J., Dupriez, V., Adams, M.E., **2003a**. Two subtypes of ecdysis-triggering hormone receptor in *Drosophila melanogaster*. *J. Biol. Chem. 278* (20), 17710–17715). (b) Phylogenetic tree depicting genes encoding the corazonin receptors from *Manduca* (MasCRZR) and *Drosophila* (DrmCRZR CG10698) and CCAP receptor (CG6111). The number of changes between each sequence is represented by the length of each branch. The percentage of 1000 bootstrap replicates supporting each node is shown. (Data from Kim, Y.J., Spalovska-Valachova, I., Cho, K.-H., Zitnanova, I., Park, Y., *et al.*, **2004**. Corazonin receptor signaling in ecdysis initiation. *Proc. Natl Acad. Sci. USA 101*, 6704–6709.)

PBAN receptor (Choi *et al.*, 2003); Kim and Adams in preparation). This receptor shows no sensitivity at all to *Manduca* or *Drosophila* ETHs. Subsequent to this work, independent characterizations of the corazonin and CCAP receptors have appeared (Cazzamali *et al.*, 2002; Staubli *et al.*, 2002).

Interestingly, none of the GPCRs in the NMU or vasopressin receptor groups have proved to be likely ETH receptor candidates. Rather, the most likely ETH receptor is CG5911, which is distantly related to the NMU group.

3.1.3.3. Ecdysis Triggering Hormone Receptors

A *Drosophila* gene related to the vertebrate TRH receptor and more distantly to the NMU receptor group is *CG5911*. This gene, cloned and heterologously expressed in CHO cells, is highly sensitive and selective to ETHs from both *Manduca* and *Drosophila* (Iversen *et al.*, 2002; Park *et al.*, 2003a). *CG5911* encodes two receptor subtypes by alternative splicing of the 3-prime exon, which are referred to as CG5911a and CG5911b (**Figure 16a**). Preliminary indications are that CG5911a and CG5911b may play different functional roles in recruitment of the ecdysis sequence, as their relative affinities for ETHs and coupling to G proteins appear to be distinct (Park *et al.*, 2003a). Although DrmETH1 and DrmETH2 are roughly equipotent against both subtypes, MasPETH appears to be a more potent activator for CG5911b than MasETH, while the converse is true for CG5911a. At higher concentrations, related peptides having the -PRXamide sequence motif also activate CG5911b, the most active of these being SCP_B, CAP2b-1, hugγ, and HezPBAN (**Figure 16b**). At still higher concentrations, the invertebrate peptide myomodulin and vertebrate peptides NMU and thyrotropin releasing hormone (TRH) activate CG5911b. This pharmacological analysis of CG5911 supports their hypothesized evolutionary relationships with TRH receptors and the NMU receptor groups that are predicted by phylogenetic analysis.

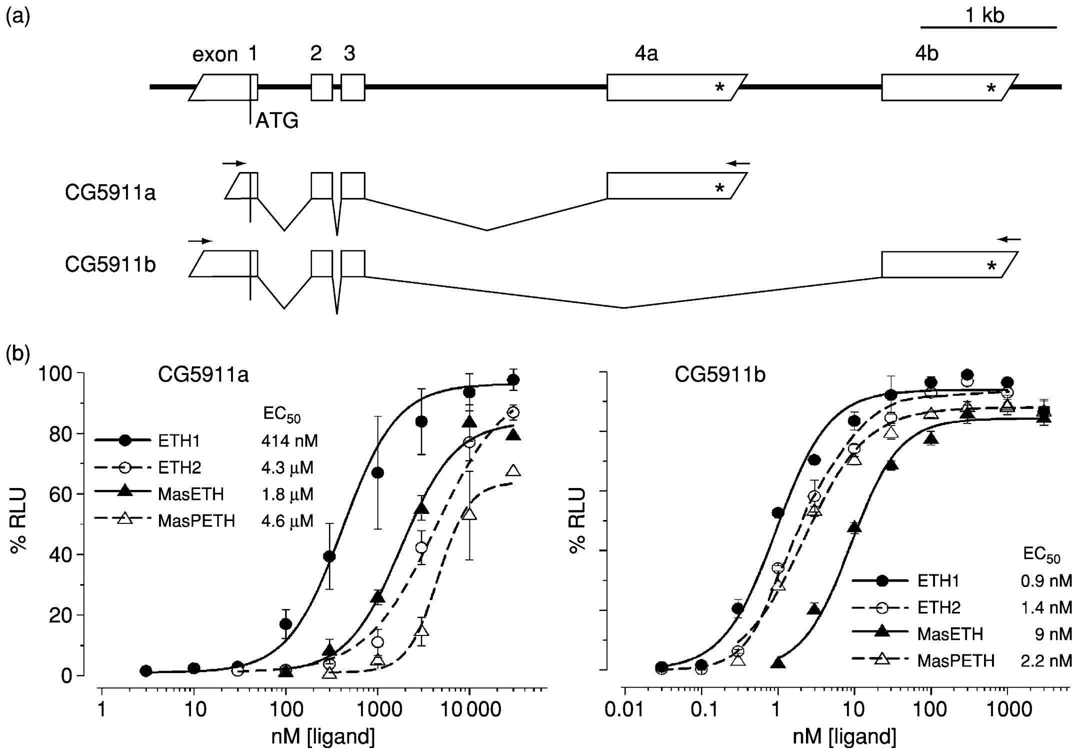

Figure 16 Organization of the ETH receptor gene and pharmacology of the ETH receptor. (a) Genomic structure of ETH receptors (CG5911a and CG5911b) arising from two alternative transcripts with different exons 4a and 4b at the 3′ end of the gene. Transcripts were confirmed experimentally by RT-PCR with the primers (arrows) located on the boundary of start and stop codons in the predicted open reading frames. Each 5′ and 3′ end of the transcript is not determined and left as a slanted rectangular of the exon boxes. (b) Pharmacology of ETH receptor subtypes A and B. Transcripts were expressed in CHO cells with the G protein Gα16 (see Park *et al.*, 2003a for details). Using this heterologous expression system, CG5911a is less sensitive to ETH peptides from *Drosophila* and *Manduca* as compared to CG5911b, perhaps due to suboptimal receptor coupling with the G protein. Note that both *Drosophila* and *Manduca* ETHs are active on both receptors. (Reproduced with permission from Park, Y., Kim, Y.J., Dupriez, V., Adams, M.E., **2003a**. Two subtypes of ecdysis-triggering hormone receptor in *Drosophila melanogaster*. *J. Biol. Chem. 278* (20), 17710–17715; © American Society of Biochemistry and Molecular Biology.)

Recent work on the cloning and expression of ETH receptors in *Manduca* indicate the presence of functional orthologs of CG5911 in the CNS (Kim, Cho, Zitnan, and Adams, in preparation). The *Manduca* receptors also occur as two subtypes through alternative splicing and exhibit pharmacological profiles that are generally consistent with those of CG5911a and CG5911b. The *Manduca* receptors show higher ligand specificity compared to their *Drosophila* counterparts. Whereas CG5911b responds to both PBAN-like *hugin* peptides, its *Manduca* ortholog is completely insensitive to PBAN or *hugin* peptides at up to 10 μM concentration. The high specificity and sensitivity of the *Manduca* receptors provides further evidence that CG5911 and its orthologs in other insects function as the physiological ETH receptors. Preliminary evidence from *in situ* hybridization work in both *Drosophila* and *Manduca* indicate the widespread occurrence of ETH receptors in central neurons located in the brain and ventral nerve cord.

3.1.3.4. Corazonin Receptors

Corazonin is a highly conserved and widespread neuropeptide in insects. Although it was initially associated with cardioacceleratory activity in the cockroach *Periplaneta* (Veenstra, 1989), such a function has not been noted in other insects. It also controls coloration changes in locusts, but again such a function has not been observed in other insects. Given its highly conserved structure across widely divergent groups of insects, it is expected to have a more universal function than has been discerned up to now. One avenue for defining such a function would be identification of cells expressing the corazonin receptor.

The *Drosophila* corazonin receptor (CG10698; DrmCRZR) occurs in the vasopressin group of GPCRs, and is related to the AKH receptor. Both receptors are thought to have evolved from a common ancestor of the vertebrate gonadotropin releasing hormone receptor (Cazzamali *et al*., 2002; Park *et al*., 2002b). Its sensitivity to corazonin is in the low nanomolar range when expressed either in *Xenopus* oocytes or CHO cells. However, studies of the *Drosophila* receptor thus far have not provided additional clues regarding the functional significance of corazonin signaling.

Recently, the DrmCRZR ortholog in *Manduca* was cloned, expressed, and localized in Inka cells of the epitracheal endocrine system as a prelude to detailed physiological studies (Kim *et al*., 2004). Corazonin receptor cDNA in *Manduca* encodes a protein of 436 amino acids with seven putative transmembrane domains. The *Manduca* corazonin receptor (Mas-CRZR) appears to bind corazonin with a higher affinity than does the *Drosophila* CRZR, with an EC_{50} value of ~200 pM when expressed in *Xenopus* oocytes and ~75 pM when expressed in CHO cells. Mas-CRZR exhibits high sensitivity and selectivity for corazonin.

Later in this chapter (Section 3.1.5.2), data showing that corazonin triggers ecdysis in *Manduca* larvae are reviewed. Following these observations, the corazonin receptor was located in Inka cells, the sole source of PETH and ETH, by Northern analyses. These findings provide further evidence implicating corazonin as an ecdysis signaling peptide upstream of PETH and ETH, and raises new questions regarding the respective roles of corazonin and EH in the peptide signaling cascade that controls this critical process in insect development.

3.1.3.5. CCAP Receptor

As mentioned in Section 3.1.3.2, the *Drosophila* gene *CG6111* encodes the likely CCAP receptor (Park *et al*., 2002b; Cazzamali *et al*., 2003). The first reported expression of this receptor was in *Xenopus* oocytes, where it responded to concentrations of CCAP above 10 nM and also showed considerable sensitivity to AKH (Park *et al*., 2002b). A different splice variant expressed in CHO cells showed much higher sensitivity and selectivity for CCAP (EC_{50} ~50 pM); no response to AKH or any other peptide was observed (Cazzamali *et al*., 2003). Differences in the potency and selectivity of these receptor isoforms may be related to the differential splicing of exon 7, or to the expression system used. A CCAP receptor ortholog with very high sequence similarity to the *Drosophila* gene was located in the *Anopheles* genome also (Cazzamali *et al*., 2003).

3.1.3.6. MIP Receptors

Using a novel expression and bioassay strategy, Taghert and colleagues deorphaned CG14484, a GPCR related to bombesin (Johnson *et al*., 2003). Instead of relying on elevation of intracellular calcium as an indication of GPCR activation, these workers utilized a β-arrestin-GFP reporter, which provides a measure of GPCR desensitization in response to ligand exposure. They showed this receptor to be sensitive to 1 μM *Drosophila* "allatostatin-B1" referred to here as *Drosophila* MIP-I (AWQSLQSSWamide).

3.1.3.7. Receptors for FMRFamide-Related Peptides

Receptors specific for several groups of FMRFamide-related peptides (FaRPs) have been recently identified in *Drosophila* and *Anopheles* (Brody and

Cravchik, 2000; Hewes and Taghert, 2001; Cazzamali and Grimmelikhuijzen, 2002; Garczynski *et al.*, 2002; Egerod *et al.*, 2003). These include receptors for peptides having C-terminal amino acid sequence motifs -FMRFa, -FLRFa, -MRFa, or -RFa, as in NPF.

Recent evidence indicates that F10, which possesses a C-terminal-FLRFa motif (**Figure 13**), can function as an ecdysis initiator upon injection into *Manduca* pharate larvae (see Section 3.1.5.1). Two *Drosophila* receptors (CG8985 and CG13803) recently cloned and expressed in CHO cells show high sensitivity and selectivity for the *Drosophila* peptide Dromyosuppressin (TDVDHVLFLRFa), the *Drosophila* homolog of F10 (Egerod *et al.*, 2003). These receptors were unresponsive to FMRFamide, *Drosophila* NPF-1 (AQRSPSLRLRFamide), and perisulfakinin (EQFDDY(SO_3H)GHMRFamide). It remains unclear how selective the receptor is for peptides ending with the –FLRFamide motif.

The FMRFamide receptor has been identified as CG2114 (Cazzamali and Grimmelikhuijzen, 2002; Meeusen *et al.*, 2002). The NPF receptor has been identified as CG1147, a member of the rhodopsin receptor family (Garczynski *et al.*, 2002). So far, neither the FMRFa nor NPF receptors and corresponding ligands have been demonstrated to take part in ecdysis signaling.

3.1.3.8. Summary

At the time of this writing, more than half of the 44 receptors predicted as peptide hormone receptors have been cloned, expressed, and associated with putative physiological ligands. The association of these receptors with high affinity ligands is the first step in defining their physiological functions.

3.1.4. Ecdysteroid Control of Gene Expression in Preparation for Ecdysis

3.1.4.1. Introduction

The transition from feeding to pharate stage during each stadium of development is induced by rising levels of ecdysteroids. This event triggers successive bouts of gene expression that have been referred to as early, early–late, and late phases, according to the appearance of sequential puffs at various positions on polytene chromosomes of *Drosophila* (Ashburner *et al.*, 1974). In this section, early and late gene expression events in *Manduca* that are involved in assembly of the peptide signaling cascade that regulates ecdysis are described. Early events that occur around the peak of ecdysteroid levels include acquisition of CNS sensitivity to ETH and increased production of ETH in Inka cells. Although Inka cells accumulate large amounts of ETH peptides during this phase, they are incapable of releasing their contents until ecdysteroids decline to low levels. Acquisition of competence to release ETH is associated with late gene expression events that occur once ecdysteroids decline to <0.1 μg ml^{-1} (Kingan and Adam, 2000).

3.1.4.2. Effects of Elevated Ecdysteroid Levels

3.1.4.2.1. Induction of CNS sensitivity to ETH In *Manduca,* only pharate stages are sensitive to PETH and ETH. Injection of these peptides into freshly ecdysed, feeding, or wandering larvae, or ecdysed pupae and adults never results in pre-ecdysis or ecdysis behaviors. Animals become sensitive and show specific behavioral responses to PETH and ETH some 1–2 days prior to ecdysis depending on the particular stage. The onset of this sensitivity has been determined for pharate 5th instar larvae and pharate pupae (Zitnan *et al.*, 1999; Zitnanova *et al.*, 2001). Pharate larvae become responsive to PETH or ETH injections at the time of peak ecdysteroid levels, which corresponds to initiation of head capsule slip (30 h prior to ecdysis). These animals respond to ETH injection with pre-ecdysis behavior only, but after the head capsule is completely slipped 2 h later, ETH injection induces the entire behavioral sequence in most animals. ETH treatment of pharate pupae elicits ecdysis behavior about 48 h prior to expected ecdysis (**Figure 17a**). These animals do not show pre-ecdysis contractions. The latency from ETH injection to the onset of ecdysis behavior is progressively shorter as animals approach the time of normal ecdysis (Zitnanova *et al.*, 2001). In *Bombyx*, sensitivity to ETH begins at 30 h prior to ecdysis of 5th instar larvae, which again corresponds to head capsule slippage, 24 h before ecdysis of nonspinning pharate pupae, and in developing adults already 6–8 days prior to eclosion (Zitnan *et al.*, 2002); Zitnan, unpublished data). These studies showed that sensitivity to PETH and ETH is correlated with the appearance of the highest ecdysteroid titers in the hemolymph (**Figure 17a**). The stage-specific differences in appearance of sensitive periods are remarkable, and reflect occurrence of the ecdysteroid peak at different times in the hemolymph during development. These results also suggest that the CNS motor program is fully competent to perform complete pre-ecdysis and ecdysis behaviors far earlier than previously indicated in experiments with EH (Copenhaver and Truman, 1982).

These aforementioned experiments lead to the hypothesis that the behavioral response to ETH is

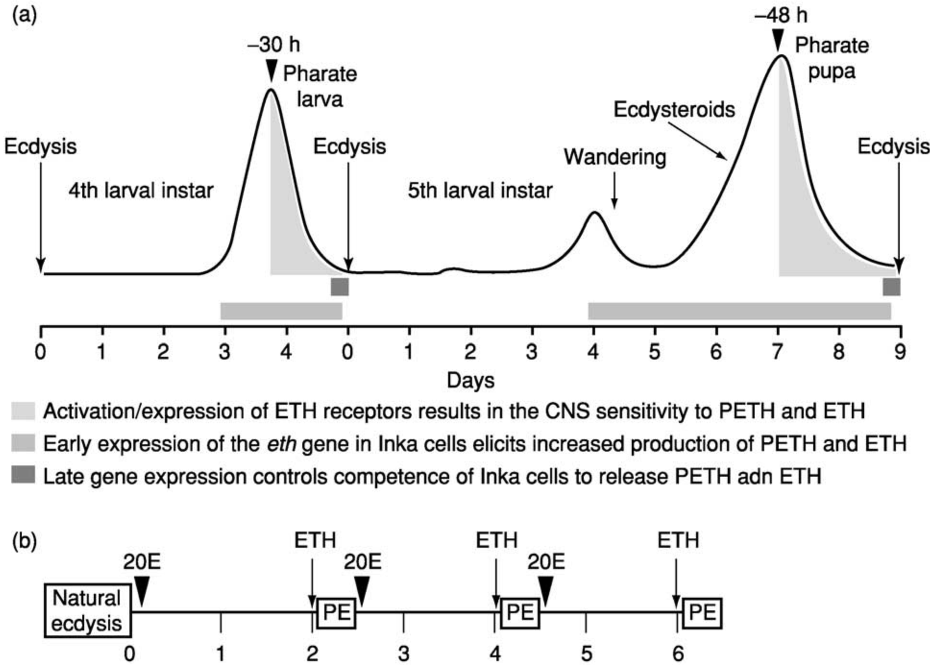

Figure 17 Ecdysteroid action on the *Manduca* CNS and Inka cells prior to larval and pupal ecdyses of *Manduca*. (a) Freshly ecdysed, feeding, or wandering larvae, which contain low ecdysteroid levels in the hemolymph are insensitive to ETH. Peak ecdysteroid levels in the hemolymph coincide with the onset of CNS sensitivity to ETH. Light grey areas illustrate time periods of CNS sensitivity to ETH. Injection of this peptide induces ecdysis sequence during this time. High ecdysteroid levels induce expression of the ETH gene, while declining ecdysteroids control secretory competence of Inka cells. (b) Injection of 20-hydroxyecdysone (20E) into isolated abdomens induces CNS sensitivity to ETH in 1–2 days. Ecdysteroid treatments (20E, arrowheads) followed by ETH injections (arrows) 2 days later induced repeated onset of pre-ecdysis behavior (PE). (Modified from Zitnanova, I., Adams, M.E., Zitnan, D., **2001**. Dual ecdysteroid action on the epitracheal glands and central nervous system preceding ecdysis of *Manduca sexta*. *J. Exp. Biol. 204* (Pt 20), 3483–3495.)

enabled by exposure to high ecdysteroid levels. To test this, *Manduca* 5th instar larvae were examined for their ability to respond to ETH injection at various stages following treatment with ecdysone, 20-hydroxyecdysone (20E), or the ecdysteroid agonist (tebufenozide, RH-5992). The results of these experiments showed that pretreatment with steroid or steroid agonist induced ETH sensitivity in freshly ecdysed intact larvae or isolated abdomens of *Manduca* within 1–2 days (Zitnanova *et al*., 2001). ETH sensitivity was detected by injection of the peptide, which induced pre-ecdysis and in some cases ecdysis behaviors in steroid treated animals. Indeed, repeated injections of 20E followed by ETH into isolated abdomens induced the behavioral response (pre-ecdysis) three times within 6 days (Figure 17b; Zitnanova *et al*., 2001). Direct action of 20E on the CNS was demonstrated by *in vitro* experiments. The CNS dissected from freshly ecdysed or feeding larvae was incubated with physiological levels of 20E for 24–28 h. Addition of ETH into the incubation medium elicited typical ecdysis bursts in dorsal nerves of these isolated nerve cords (Zitnan *et al*., 1999; Zitnanova *et al*., 2001).

These experiments suggest that ecdysteroids act directly on the CNS to induce sensitivity to ETH. Mechanisms controlling ecdysteroid-induced CNS sensitivity to ETH are not known. However, it seems likely that high ecdysteroid concentrations cause expression of the PETH and ETH receptors in the CNS, or alternatively some critical downstream step in signal transduction pathways leading to activation of these receptors.

3.1.4.2.2. Stimulation of ETH synthesis in *Manduca* and *Bombyx* During ecdysis, Inka cells release most, if not all, of their peptide stores. Depletion of peptide stores is accompanied by a corresponding decrease in cell volume. Following ecdysis, cell volume and PETH and ETH content increase gradually during the subsequent feeding stage. A sharp increase in PETH and ETH production occurs upon appearance of ecdysteroids to signal onset of the next molt. The concomitant rise of hemolymph ecdysteroids and HPLC-purified peptides in Inka cells has been quantified by enzyme immunoassays in *Manduca* pharate 5th instar larvae. Elevation of peptide content in Inka cells was

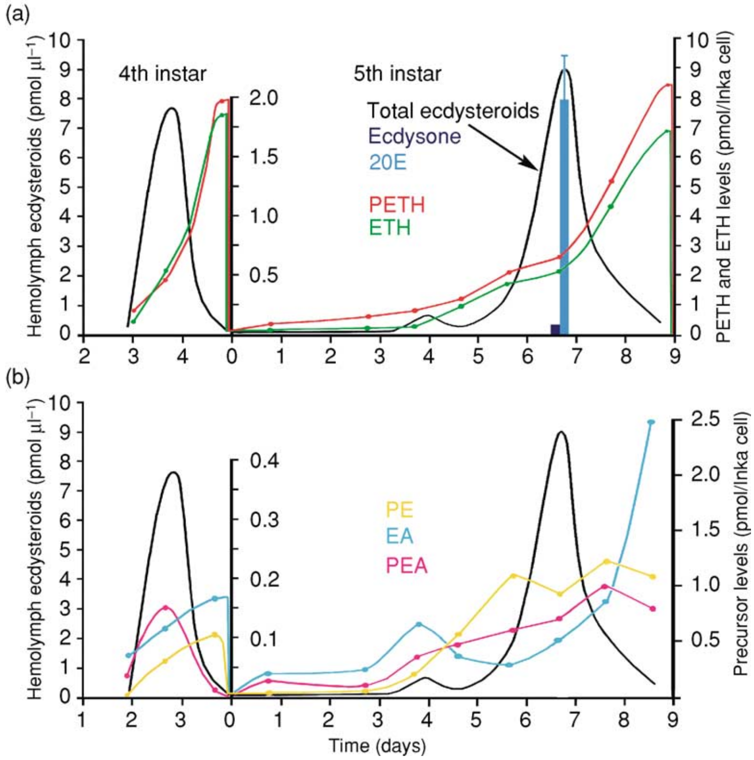

Figure 18 Ecdysteroids stimulate production of PETH, ETH, and their precursors in *Manduca* Inka cells. (a,b) Only small amounts of peptides and their precursors are present in Inka cells during low ecdysteroid levels in 4th and 5th instar larvae. Elevation in ecdysteroid levels is associated with increased production of PETH, ETH, and all precursor forms (PE, EA, PEA). Fully processed peptides and EA reached the highest levels on the last day of each instar, while levels of PE and PEA decreased prior to each ecdysis due to precursor processing. The ratio of ecdysone and 20E in the prepupal peak (5th instar) was 1:20. Each peptide determination represents the mean ± SD of 3–4 sets of 20–40 epitracheal glands. Each ecdysteroid determination represents the mean ± SD of 5–11 hemolymph samples. (Adapted from Zitnan, D., Ross, L.S., Zitnanova, I., Hermesman, J.L., Gill, S.S., *et al.*, **1999**. Steroid induction of a peptide hormone gene leads to orchestration of a defined behavioral sequence. *Neuron 23* (3), 523–535, and Zitnanova I., Adams, M.E., Zitnan, D., **2001**. blocked by pretreatment with the transcription inhibitor actinomycin D, indicating the requirement for renewed gene expression (Zitnan *et al.*, 1999). Likewise, onset of the wandering stage and molt of 5th instar *Manduca* larvae involves sharp increases in the rate of PETH and ETH synthesis immediately after each of two successive ecdysteroid pulses (**Figure 18**; Zitnanova *et al.*, 2001). Interestingly, levels of peptide precursors also increased sharply following each steroid pulse, but quickly decreased as they were enzymatically processed to PETH and ETH (**Figure 18**). Consistent with this, injection of 20E or the steroid analog tebufenozide (RH5992) induced expression of the ETH gene and increased production of peptide hormones and their precursors in Inka cells (Zitnanova *et al.*, 2001). These results show that steroid pulses induce sharply increased rates of Inka cell peptide production. This increased expression activity sets the stage for ecdysis behavior at the end of the molt.

3.1.4.2.3. Stimulation of ETH synthesis in *Drosophila* Preliminary studies indicate that, consistent with events described in *Manduca* and *Bombyx*, steroids regulate *eth* expression and ETH production in *Drosophila* (Filippov, Adams, and Gill, unpublished data). ETH production was observed in a transgenic *Drosophila* line, in which an enhanced green fluorescent protein reporter (*egfp*) gene was placed under the control of the *eth* promoter (Park *et al.*, 2002a). Transformed flies exhibited expression of *egfp* only in Inka cells and paralleled expression of *eth*. Therefore, the reporter gene *in vivo* had all the necessary regulatory elements for proper gene expression. When these flies were crossed with the temperature sensitive ecdysone mutant *ecd1* (Berreur *et al.*, 1984), markedly lower expression of *egfp* occurred at the nonpermissive temperature where ecdysone production is suppressed. In particular, a fourfold decrease of reporter gene expression was observed in the absence of the

ecdysone peak that normally occurs during the third instar. These observations indicated that expression of *eth* requires ecdysone. However, attempts to rescue *eth* expression in these deficient larvae by administration of ecdysone failed, indicating that additional factors apparently are required (Filippov, Adams, and Gill, unpublished data).

Further experiments monitored expression of the ETH gene in the embryonic *Manduca* cell line GV1, which was shown to be responsive to ecdysteroid induction (Lan *et al*., 1997). Though the *eth* gene has a strict Inka cell specific expression *in vivo* (Park *et al*., 2002a), it was expressed at low-levels in this cell line. This low-level transcriptional activity of the *eth* gene provided a convenient system to test whether the *eth* promoter is responsive to ecdysteroids. Incubation of the GV1 cells with 1 μM 20E did not change the level of the *eth* gene transcription. As a positive control the expression of the *MsE75* gene, a transcriptional factor encoded by one of the early primary response genes, was enhanced by 20E. These observations indicated that the *eth* promoter in GV1 cells does not respond directly to ecdysone induction, again suggesting that other regulatory factors, possibly unique to the Inka cell, might be involved. In summary, regulation of *eth* gene expression appears to be ecdysone (20E) dependent, but a model based on a direct ecdysone regulatory mechanism (Zitnan *et al*., 1999) requires further study.

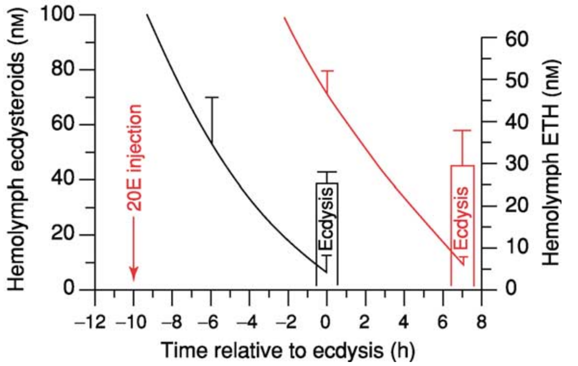

Figure 19 Ecdysteroid decline in the hemolymph is required for ETH release from *Manduca* Inka cells. In normal larvae, ecdysteroid decline to very low levels (black line) leads to ETH secretion (black bar) and onset of the ecdysis sequence at 0 h. Injection of 10 μg 20-hydroxyecdysone (20E) 10 h prior to ecdysis (red arrow) delays ETH release and ecdysis for 6–8 h (red bar). 3.1.4.3. Effects of Declining Ecdysteroids

3.1.4.3.1. Declining ecdysteroids enable secretory competence in Inka cells High ecdysteroid levels that initiate the molt and coordinate gene expression in preparation for the next stage also serve to inhibit onset of the ecdysis sequence. This was first demonstrated by experiments in which prolongation of high steroid levels delayed ecdysis (Slama, 1980; Truman *et al*., 1983; Curtis *et al*., 1984). However, the CNS is capable of responding to ETH by playing out the ecdysis sequence as early as 1–2 days prior to natural ecdysis, which marks the peak of ecdysteroid levels (Zitnan *et al*., 1999). It is now clear that high ecdysteroid levels inhibit ecdysis by preventing ETH release from Inka cells (Kingan and Adams, 2000).

A decline in ecdysteroid levels is necessary for ecdysis to proceed (**Figure 19**). In *Manduca*, the onset of ecdysteroid decline coincides with loss of MIP-IR from the epiproctodeal glands (Davis *et al*., 2003). When ecdysteroids drop to below 0.1 μg ml^{-1}, Inka cells become competent to release ETH. Inhibition of ecdysis by elevated ecdysteroid levels may be a failsafe method that prevents life-threatening premature ecdysis. In pharate pupae of *Manduca*, Inka cells challenged with EH acquire competence to respond with ETH release about 8 h before pupation. Injection of 20-hydroxyecdysone (20E) into precompetent insects delays this acquisition of competence, even though EH evokes accumulation of the second messenger cGMP in Inka cells. This demonstrates that the EH receptor is present in the Inka cell at an early stage, and that secretory competence involves a signaling step downstream of receptor activation. Precompetent glands transferred from a high ecdysteroid environment into steroid-free culture medium acquire competence within about 12 h, but this can be prevented by inclusion of 20E above 0.1 μg ml^{-1} (Kingan and Adams, 2000). Actinomycin D completely inhibits acquisition of competence, showing its dependence on transcriptional events. These findings indicate that declining ecdysteroids trigger late transcriptional events in Inka cells, the product of which is an ETH secretion enabling process downstream of EH receptor activation and cGMP accumulation (Kingan and Adams, 2000).

The low levels of 20E ($\leq$0.1 μg ml^{-1}) permissive for acquisition of competence correspond to those that allow expression of β-FTZ-F1, a transcription factor whose expression occurs in response to high followed by low ecdysteroid levels (Lavorgna *et al*., 1993; Hiruma and Riddiford, 2001). β-FTZ-F1 is implicated in acquisition of competence of various tissues to respond to hormonal cues, including competence of salivary glands to degenerate at

the end of the prepupal period and in the formation of normal cuticle at the end of each molt (Yamada *et al.*, 2000). Interestingly, flies that are either deficient in β-FTZ-F1 or that express it prematurely are unable to undergo successful ecdysis, and show a "double mouth hook" phenotype characteristic of ecdysis deficiency (see also Section 3.1.5.3). The timing of β-FTZ-F1 expression in *Manduca* (Hiruma and Riddiford, 2001) closely corresponds to the period during which Inka cells acquire competence to secrete ETH (Kingan and Adams, 2000), indicating that β-FTZ-F1 might be involved in this process.

3.1.4.3.2. Ecdysteroid decline and VM cell excitability The decline of ecdysteroid levels during the hours preceding ecdysis appears to be critical in the timing of EH release (Johnson *et al.*, 2003). Electrophysiological experiments have shown that the ecdysteroid decline is followed by elevated excitability of the VM neurosecretory cells that produce EH (Hewes and Truman, 1994). Intracellular recordings from these cells showed that they are not spontaneously active either during the feeding stage, when steroid levels are low, or during the early pharate stage, when steroids rise to peak levels. In contrast, subsequent ecdysteroid decline at the end of the pharate stage was followed by increased excitability of the VM neurons. Excitability of these neurons was assayed about 1 h prior to expected ecdysis. Prolongation of elevated ecdysteroid levels by injection of 20E considerably delayed the appearance of excitability in VM neurons. Likewise, treatment with the RNA synthesis inhibitor, actinomycin D (AcD) at the appropriate time (about 6 h prior to ecdysis) blocked VM activity and the ability to release EH. These experiments suggest that late gene transcription induced by ecdysteroid decline is responsible for excitability of VM cells and consequent release of EH (Hewes and Truman, 1994).

A critical factor complicating interpretation of the Hewes and Truman work on VM excitability is the discovery that circulating ETH triggers onset of the ecdysis behavioral sequence about 1 h prior to ecdysis through direct actions on the CNS (Zitnan *et al.*, 1996, 1999). One cellular target of ETH in the CNS appears to be the VM neurons, since their exposure to ETH increases excitability and causes spike broadening (Gammie and Truman, 1999). Hewes and Truman examined VM neuron excitability 0.9 h prior to ecdysis, which is precisely when ETH levels rise in the hemolymph to initiate pre-ecdysis. It is therefore possible that increased VM excitability during the hour prior to ecdysis is caused by ETH.

3.1.5. Regulation of ETH Release

3.1.5.1. Corazonin Elicits Initial Release of PETH and ETH

Recent studies have led to the surprising discovery that, besides EH, additional factors from the CNS induce and midgut induce Inka cell release of ETH. During a search for ETH activity in tracheal extracts of different insects, midgut extracts were employed as intended "negative" controls. Surprisingly, midgut extracts of *Manduca, Bombyx*, *Tenebrio*, *Aedes*, and *Drosophila* larvae induced pre-ecdysis in 20–40 min followed in some cases by ecdysis behavior when injected into *Bombyx* pharate larvae. The relatively long latencies for pre-ecdysis initiation indicated that the midgut factors might act through the release of ETH from Inka cells. Factors with similar activities were found in HPLC-purified extracts of the CNS (Spalovska-Valachova, Takac, Zitnan, unpublished data).

One of the peptides in the CNS extracts has been identified as corazonin (pQTFQYSRGWTNamide; see Section 3.1.2.7). Recent experiments show that corazonin induces pre-ecdysis and ecdysis in pharate larvae of *Manduca*, through a direct action on Inka cells, which express the corazonin receptor and respond to picomolar concentrations of corazonin by secreting PETH and ETH *in vivo* and *in vitro*. Corazonin release into the hemolymph just prior to pre-ecdysis initiation was demonstrated by a sensitive assay using a CHO cell line expressing the corazonin receptor (Kim *et al.*, 2004). These data indicate that corazonin induces initial release of PETH and ETH from Inka cells, which then act on the CNS to activate pre-ecdysis and ecdysis behaviors. Similar results were obtained with corazonin injected into *Bombyx* pharate larvae.

Additional circumstantial evidence for involvement of corazonin in ecdysis control comes from earlier studies (Copenhaver and Truman, 1986b, 1986c). These authors demonstrated "EH activity" in nine ipsilateral brain neurosecretory cells called type Ia, which transport their contents to the CC–CA. Extracts of these cells induced premature onset of ecdysis when injected into *Manduca* pharate larvae. Moreover, electrical stimulation of CC nerves (NCC 1,2) led to a marked increase of "EH activity" released into the medium (Copenhaver and Truman, 1986b, 1986c). Since a subset of type Ia cells (five pairs of type Ia_2 cells) reacted with the antiserum to EH, it was concluded that the activity originated from these neurons. However, later studies revealed that EH is only produced in the brain ventromedial neurons (VM; type V), which do not project to the CC–CA complex in larvae and

pharate pupae (Horodyski *et al.*, 1989; Kamito *et al.*, 1992; Riddiford *et al.*, 1994). Since extracts of ipsilateral cells contained both cell types (Ia_1 and Ia_2), the observed "EH activity" was very likely induced by corazonin and FLRFamide (F10), which are produced in Ia_1 cells and released through the CC–CA complex.

Determination of various FLRFamide levels in different ganglia and neurohemal organs suggest the release of these neuropeptides at ecdysis (Miao *et al.*, 1998). The authors further propose that FLRFamides may modulate contractions of skeletal and visceral muscles during pre-ecdysis and ecdysis behaviors. Recent unpublished results indeed demonstrate that injection of *Manduca* pharate larvae (−6 h) with F10 or its extended isoforms F24 and F39 induces pre-ecdysis and ecdysis within 30–40 min (Spalovská, Zitnan, Kingan and Adams, unpublished data).

Thus, in addition to EH, peptides from the CNS and midgut appear to be involved in regulation of the ecdysis behavioral sequence. These structurally diverse peptides probably control different functions during ecdysis behaviors, but have one thing in common: they act on Inka cells to ensure that their entire hormonal content is completely released during the ecdysis sequence.

3.1.5.2. Eclosion Hormone Elicits Depletion of Inka Cells

3.1.5.2.1. Timing of EH release and action on Inka cells Stereotypic pre-ecdysis and ecdysis behaviors are driven by central pattern generators intrinsic to the CNS. Induction of these behaviors was originally attributed to action of EH on the circadian gated adult eclosion (Truman and Sokolove, 1972). Thus, injection of EH initiates adult eclosion and also ecdysis in earlier instars, but only during a relatively narrow window of sensitivity that arises close to the time of natural ecdysis. (Reynolds *et al.*, 1979; Copenhaver and Truman, 1982; Weeks and Truman, 1984a, 1984b; Truman, 1985). For example, pharate pupal *Manduca* become sensitive to EH at ~8 h prior to natural ecdysis. The CNS was viewed for many years as the likely target for the hemolymph-borne EH. Evidence for this came from experiments demonstrating that semi-isolated ventral nerve cords, when treated with corpora cardiaca extracts containing EH, generate patterned motor output consistent with pre-ecdysis and ecdysis behaviors (Weeks and Truman, 1984a). However, the success of these experiments depended on the presence of an intact tracheal system, ostensibly to oxygenate the highly aerobic nervous system.

It is now recognized that the fully isolated CNS does not respond to hemolymph-borne EH, and that its inability to trigger ecdysis behaviors when injected prior to this sensitive period is due to a lack of competence in Inka cells to release ETH. Recent investigations have shown clearly that EH triggers release of the ETH from Inka cells *in vitro*, but only when they are dissected no earlier than 7–8 h prior to pupation (Kingan *et al.*, 1997a). This time corresponds precisely to *in vivo* EH sensitivity in pharate pupae. Indeed, the requirement for the tracheal system for EH action on the CNS *in vitro* is due to the obligatory presence of a segmentally distributed endocrine system of Inka cells attached to the tracheal tubes near each spiracle (Zitnan *et al.*, 1996). Hemolymph-borne EH is apparently acting on Inka cells to induce the release of PETH and ETH. The beginning of sensitivity to EH and the latencies from injection to behavioral onset in *Manduca* pharate 2nd and 5th instar larvae, pharate pupae, and pharate adults have been described (Reynolds *et al.*, 1979; Copenhaver and Truman, 1982; Truman, 1985; Ewer *et al.*, 1997). Further studies have established that EH is a potent releaser of ETH from Inka cells, and provides a mechanism for the complete depletion of ETH necessary for the transition from pre-ecdysis to ecdysis behavior (Kingan *et al.*, 1997a).

The latency between EH injection and the appearance of ecdysis depends on the stage and time of injection. For example, in the pharate larva, injection of CC–CA extracts containing EH, corazonin, and other neuropeptides 12 h prior to normal ecdysis initiates pre-ecdysis 2–3 h later. However, the onset of ecdysis behavior is not accelerated unless injections are made 3–6 h prior to normal ecdysis. Pre-ecdysis resulting from early injections is often weak and interrupted by quiet periods, and is followed by ecdysis only after several more hours (Copenhaver and Truman, 1982). If injections of extracts containing EH are made closer to the time of normal ecdysis, the latency is correspondingly reduced; injections 2–3 h before normal ecdysis show strong pre-ecdysis behavior within 15–25 min, with ecdysis following about 1 h later. Similar results were obtained with pharate pupae (Truman, 1985). The long latency from hormone injection to appearance of the behavior suggests that EH triggers a cascade of downstream events culminating in ecdysis (Truman, 1992). The longer latencies and weaker behaviors that arise when EH is injected early also suggest that this peptide persists in the hemolymph for hours after injection, but that levels remaining at the time Inka cells are capable of responding are close to the threshold for eliciting behavior.

The natural release of EH into the hemolymph during the ecdysis sequence is somewhat controversial, and difficult to pinpoint with certainty given its very low, biologically active concentration (~2–10 pM; Kingan *et al.*, 1997a). Some clues to the appearance of EH in the hemolymph are provided by the signature appearance of cGMP in Inka cells some 20 min after the onset of pre-ecdysis in *Manduca* larvae (Ewer *et al.*, 1997). Prior to this time, hemolymph levels of ETH are low, but sufficient to cause pre-ecdysis. The appearance of cGMP in Inka cells corresponds to the steep elevation of PETH and ETH in the hemolymph, known to occur upon exposure of Inka cells to EH *in vitro* (Kingan *et al.*, 1997a). These observations suggest that EH is released into the hemolymph about 20–30 min after the onset of pre-ecdysis to induce cGMP production in Inka cells and depletion of PETH and ETH. Also, concomitant loss of EH-immunoreactivity in larval proctodeal nerves, which are neurohemal organs for EH, suggests that this peptide is released at this time (Novicki and Weeks, 1996; Zitnan and Adams, 2000).

3.1.5.2.2. Signal transduction in EH-induced Inka cell secretion EH causes release of ETH from Inka cells *in vitro* at threshold concentrations of ~3–10 pM (Kingan *et al.*, 1997a). EH also elevates cGMP in Inka cells at concentrations similar to those that cause ETH release, and both cGMP and 8-Br-cGMP mimic the action of EH. The *in vitro* secretory response to EH occurs during a narrow window of development, beginning ~8 h prior to pupal ecdysis, which corresponds to the behavioral sensitivity observed previously *in vivo*. However, EH can cause cGMP elevation in epitracheal glands long before they acquire competence to release ETH, suggesting that the EH receptor and initial steps in the signal transduction cascade are in place early in development, well before the behavioral response appears (Kingan *et al.*, 1997a). The absence of a downstream step in the cascade apparently prevents secretion. During natural ecdysis, cGMP levels in Inka cells show an abrupt elevation ~30 min after onset of pre-ecdysis, well after ETH secretion has been initiated. ETH secretion therefore can be viewed as a two-step process, beginning at pre-ecdysis prior to cGMP elevation, followed by a massive release resulting from a logarithmic elevation of cGMP.

EH-induced signal transduction in Inka cells has been examined in some detail, but a full understanding of these events is incomplete at this time (Kingan *et al.*, 1997a; Kingan *et al.*, 2001; Morton and Simpson, 2002). A unique soluble, NO-insensitive guanylate cyclase, MsGC-β3, has been implicated as the likely enzyme mediating the EH-induced elevation of cGMP in target tissues (Morton and Simpson, 2002). When expressed heterologously in COS cells, MsGC-β3 exhibits significant constitutive activity that is not affected by the standard inhibitor of vertebrate soluble guanylate cyclases, ODQ (1*H*-(1,2,4)oxadiazolo(4,3-*a*)quinoxalin-1-one; Nighorn *et al.*, 1999). The constitutive activity of MsGC-β3 and its insensitivity to NO donors fits the pharmacological profile for EH action on the Inka cell (Kingan *et al.*, 2001), as well as for a group of specialized cells in the sub-transverse nerve region (Morton and Simpson, 2002).

Assuming that MsGC-β3 is responsible for EH-induced cGMP elevation, how is the EH receptor coupled to this soluble enzyme? EH-induced cGMP increases and ETH release from Inka cells are blocked by the specific protein kinase C (PKC) inhibitors tamoxifen and calphostin C (Kingan *et al.*, 2001). While these data suggest that PKC is involved in the activation of MsGC-β3, Kingan *et al.* (2001) found that the cGMP response to EH was unaffected by staurosporine, a broad spectrum kinase inhibitor, causing some uncertainty as to whether PKC is necessary for cyclase activation.

A possible role for IP_3 was also demonstrated by measurement of intracellular calcium in Inka cells following exposure to EH (Kingan *et al.*, 2001). Cytoplasmic calcium increases within 30–120 s of Inka cell exposure to EH, and remains elevated for at least 10 min, corresponding to the time-course of secretion. Since ETH secretion can occur in the absence of extracellular calcium, cytoplasmic calcium elevation presumably originates from intracellular stores. Secretion is increased in a dose dependent manner by the Ca^{2+}-ATPase inhibitor thapsigargin, a treatment that does not elevate glandular cGMP above basal levels. The secretory response to EH is partially inhibited in glands loaded with EGTA, while cGMP levels are unaffected. These findings show that EH activates second messenger cascades in the Inka cell leading to cGMP accumulation and Ca^{2+} mobilization.

In summary, the precise mechanism of cGMP elevation in EH-stimulated Inka cells remains unclear. It could be that phospholipase C activation by EH receptors produces PKC, which in turn activates soluble guanylate cyclase. This model posits PKC activation and calcium liberation upstream of cGMP activation (Morton and Simpson, 2002). However, the inability of broad-spectrum kinase inhibitors such as staurosporine to block cGMP elevation leaves open the possibility of alternative pathways, which are not yet identified (Kingan *et al.*, 2001). The model of Kingan *et al.* (2001; **Figure 30**)

includes activation of protein kinase G (PKG) and protein phosphorylation downstream of cGMP elevation as a parallel pathway with calcium elevation, both of which contribute to ETH secretion. Considerable future work is needed to clarify how cGMP and calcium act to effect release of ETH during the ecdysis sequence.

3.1.6. Orchestration of the Ecdysis Sequence

Insect development from larva to adult involves repeated shedding of old cuticle via a set of hormonally regulated motor movements called the ecdysis sequence. The endocrinology and physiology underlying ecdysis have been studied extensively in several species of moths, which pass through various larval stages and a pupal stage prior to reaching the winged, reproductive adult stage. These include the tobacco hornworm, *Manduca* (Copenhaver and Truman, 1982; Truman, 1985; Zitnan *et al.*, 1996, 1999), giant silkmoths *Hyalophora* and *Antheraea* (Truman, 1972; Truman and Sokolove, 1972; Truman and Riddiford, 1974), and the silkworm *Bombyx* (Adams and Zitnan, 1997; Zitnan *et al.*, 2002). Recent studies have also described the ecdysis sequence in *Drosophila*, where available genetic tools have permitted studies of EH-, ETH-, and CCAP-deficient flies (McNabb *et al.*, 1997; Baker *et al.*, 1999; Park *et al.*, 1999, 2002a, 2003b).

3.1.6.1. Natural and Peptide-Induced Behaviors in *Manduca*

3.1.6.1.1. Embryonic ecdysis behavior During normal development, *Manduca* larvae undergo one embryonic and four postembryonic ecdyses. PETH and ETH production in Inka cells is detectable in embryos at about 45% of embryonic development by enzyme immunoassay and immunohistochemical staining. Peptide levels in these cells reach a peak at about 65% of development. Embryonic ecdysis at 65–70% coincides with depletion of PETH and ETH immunoreactivity in Inka cells indicating that these peptides have been released into the hemolymph. Dissected embryos respond to ETH injection by showing rhythmic contractions that result in sloughing of the embryonic cuticle. These experiments suggest that ETH controls embryonic ecdysis in *Manduca*. By contrast, larval hatching behavior is not associated with ETH release (Hermesman and Adams, unpublished data).

3.1.6.1.2. Natural and ETH-induced larval ecdysis sequence Morphological markers useful for determining the time to ecdysis onset in pharate 2nd to 5th instar *Manduca* larvae have been described (Copenhaver and Truman, 1982; Zitnanova *et al.*, 2001) and are summarized in **Table 1**. The natural ecdysis behavioral sequence in *Manduca* larvae is composed of three distinct patterns initiated in the following order: pre-ecdysis I, pre-ecdysis II, and ecdysis (Weeks and Truman, 1984a, 1984b; Miles and Weeks, 1991; Zitnan *et al.*, 1999). Observations of natural behavior indicate that larvae show occasional weak, dorso-ventral contractions of the last two abdominal segments for 2–5 min interrupted by ~5 min quiet periods within 30 min (designated as intermittent pre-ecdysis I) before launching into robust, continuous pre-ecdysis I behavior. Pre-ecdysis I is characterized by synchronous dorsoventral contractions of all abdominal segments (**Figure 20**), and lasts for 60–70 min (**Figure 21**).

About 20 min after onset of pre-ecdysis I, larvae initiate pre-ecdysis II (posterioventral and proleg contractions) and continue with both behaviors for

Table 1 Timelines of morphological markers in *Manduca sexta*

Time before ecdysis (h)	*Morphological marker*
Pharate 5th instar larva	
30	Molting fluid accumulation in the prothorax followed by slippage of the old head capsule
28	''Head capsule slip'' (HCS), slippage of the old head capsule is completed
10	''Yellow mandibles,'' yellow pigmentation of new mandibles
8	''Brown mandibles,'' darkening of brown mandibles
4–6	Resorption of molting fluid and appearance of air in the old head capsule

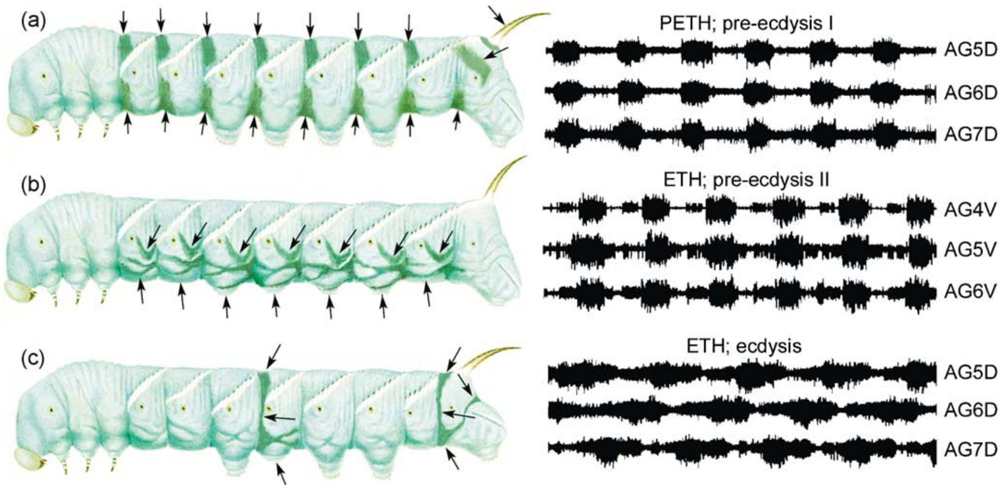

Figure 20 The ecdysis sequence of *Manduca* pharate larvae *in vivo* and *in vitro*. (a) PETH-induced pre-ecdysis I composed of synchronous dorsoventral contractions of abdominal segments (arrows; shaded areas depict muscle attachments) and corresponding synchronous bursts in dorsal nerves of abdominal ganglia 5–7 (AG5,6,7D) of the isolated nerve cord. (b) ETH-induced pre-ecdysis II characterized by posterioventral and proleg contractions (arrows) and corresponding bursts *in vitro* in ventral nerves (AG4,5,6V). (c) Ecdysis peristaltic abdominal contractions associated with proleg retractions (arrows), which result in shedding of the old cuticle and tracheae. Isolated nerve cord shows corresponding ecdysis bursts in dorsal ganglia (AG5,6,7D). (Modified from Zitnan, D., Adams, M.E., **2000**. Excitatory and inhibitory roles of central ganglia in initiation of the insect ecdysis behavioural sequence. *J. Exp. Biol. 203*, 1329–1340.)

about 40 min (Figure 21). During this time, posterioventral and proleg contractions alternate with dorsoventral contractions (Figure 20). About 1 h after initiation of pre-ecdysis I, larvae switch to ecdysis behavior, characterized by successive anteriorly directed peristaltic movements of abdominal segments and proleg retractions (Figure 20). Ecdysis movements last for about 10–12 min (Figure 21), serving first to rupture the old cuticle along the anterior midline of the thorax and subsequently to shed the cuticle with attached old tracheae.

Injection of PETH and ETH elicits pre-ecdysis and ecdysis behaviors identical to those observed under natural conditions. Likewise, exposure of the isolated CNS to these peptides elicits motor patterns closely corresponding to *in vivo* behaviors (Zitnan *et al*., 1999; Zitnan and Adams, 2000). These studies confirm that PETH and ETH activate pre-ecdysis and ecdysis behaviors organized within the CNS by central pattern generators.

In *Manduca*, there are clear differences in the overall actions of PETH and ETH. Injection of PETH into pharate larvae elicits pre-ecdysis I only (Figures 20 and 21). PETH-injected animals show pre-ecdysis I behavior for about 35–60 min and fail to advance to pre-ecdysis II or ecdysis, regardless of the dose administered (Zitnan *et al*., 1999). Corresponding pre-ecdysis I synchronous bursts in AGs are recorded *in vitro* from the isolated CNS exposed to PETH (Figure 20). Larvae injected with PETH (100–500 pmol) are unresponsive to further treatment with this peptide, but respond to ETH by initiating pre-ecdysis II followed by ecdysis (Figures 20 and 21). In contrast, naive larvae injected with ETH alone initiate pre-ecdysis I and pre-ecdysis II simultaneously, followed by ecdysis behavior. Similar results are obtained upon exposure of the isolated CNS *in vitro* (Zitnan *et al*., 1999; Figure 20). Thus, ETH can elicit the entire sequence consisting of pre-ecdysis I, pre-ecdysis II, and ecdysis.

Initiation of pre-ecdysis I and II involves direct actions of hemolymph-borne PETH and ETH on each abdominal ganglion. Pre-ecdysis I behavior is driven by a single pair of ascending interneurons whose cell bodies are located in the posterior region of the TAG, the IN-402 cells. They form monosynaptic connections with MN-2,3 in each abdominal ganglion to cause synchronous bursting (Miles and Weeks, 1991; Novicki and Weeks, 1993, 1995). Transection of the ventral nerve cord abolishes patterned bursting of MN-2,3 rostral to the cut, consistent with ascending input from these interneurons (Novicki and Weeks, 1993). In the case of PETH-injected animals exhibiting pre-ecdysis I, transection of connectives anterior to AG-7 or AG-6 leads to prolonged dorsoventral contractions in rostral abdominal segments *in vivo*. Similar results are obtained from isolated CNS following PETH exposure *in vitro*: transection of connectives leads to prolonged motor bursts in ganglia rostral to the cut (Zitnan and Adams, 2000). These findings indicate that activation of PETH receptors in each abdominal

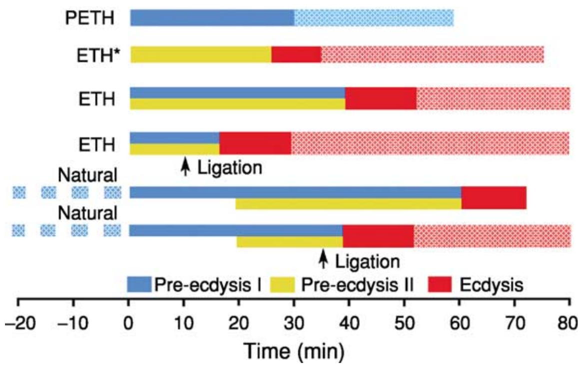

Figure 21 Timelines of natural and peptide-induced pre-ecdysis and ecdysis behaviors in *Manduca*. PETH injection into pharate 5th instar larvae induces only pre-ecdysis I behavior for about 30 min, but it can last for up to 1 h (stippled line). These larvae do not respond to further PETH treatment, but subsequent ETH injection (ETH*) induces pre-ecdysis II and ecdysis behaviors. However, naive larvae injected only with ETH initiate pre-ecdysis I and II simultaneously, followed by ecdysis movements about 40 min later. These animals cannot shed their cuticle, so ecdysis contractions last for up to 1 h. Ligation between abdominal segments 1–2 and removal of all anterior segments at 10–15 min into pre-ecdysis greatly accelerates initiation of ecdysis. The natural ecdysis sequence starts with occasional weak dorsoventral contractions in posterior abdominal segments (broken stippled squares). Continuous strong dorsoventral contractions are considered as the initiation of normal pre-ecdysis I indistinguishabe from PETH-induced behavior. About 20 min later animals initiate posteriolateral and proleg contractions (pre-ecdysis II) alternating with pre-ecdysis I compressions exactly like ETH injected larvae. Ecdysis behavior is initiated about 1 h later and lasts 12–15 min. After the cuticle is completely shed, ecdysis movements immediately stop. Ligation of larvae 35–40 min into natural pre-ecdysis accelerates ecdysis onset similarly as described above.

ganglion leads to bursting activity in interneurons and motor neurons, with the IN-402 providing the necessary input for normal synchronized rhythmic contractions (Novicki and Weeks, 1995). The IN-402 cells probably produce acetylcholine (Novicki, personal communication), but other central neurotransmitters or neuromodulators, which may control pre-ecdysis I activity are not known. IN-402 and MN2,3 retain their intrinsic properties and strength of synaptic connections in pharate pupae, indicating that weakening of pre-ecdysis in this stage is caused by other unknown components of this behavior (Novicki and Weeks, 2000).

In contrast to pre-ecdysis I, where motor neurons in each abdominal ganglion (AG) are slaves to ascending interneurons from the TAG, the pacemaker(s) for pre-ecdysis II reside in each ganglion, such that motor bursts occur independent of inputs from other ganglia. Ligation or transection of connectives between various AGs does not affect proleg and posterioventral contractions during pre-ecdysis II, and individually isolated AGs produce patterned bursting similar in duration and frequency to that recorded in intact nerve cords (Zitnan and Adams, 2000). Interneurons and neurotransmitters controlling pre-ecdysis II have not been identified, but it seems likely that the principal and accessory planta retractor motoneurons (PPRM, APRM) involved in proleg retractions during ecdysis also participate in similar contractions during pre-ecdysis II (Weeks and Truman, 1984b). The ability of ETH to elicit pre-ecdysis II contractions in isolated abdominal ganglia indicates the presence of receptors for this peptide in each ganglion as well.

3.1.6.1.3. Activation and initiation of ecdysis by central factors (cGMP, EH, CCAP, and MIPs)

Ecdysis activation in *Manduca* coincides with elevation of cyclic 3′,5′-guanosine monophosphate (cGMP) in neurosecretory cells 27 and interneurons 704 (27/704) residing in the SG, TG1–3, and AG1–7 (Ewer *et al.*, 1994, 1997). Intracellular recordings in thoracic cells 27 of *Manduca* showed that production of cGMP is associated with excitability of these neurons (Gammie and Truman, 1997b). The production of cGMP in a homologous network of 27/704 neurons was also detected at ecdyses of other unrelated insects, including silverfish, locust, cricket, mealworm beetle, and mosquito, but not in the fruitfly *Drosophila* (Ewer and Truman, 1996). These data indicate that cGMP is associated with activation of ecdysis neurons in many insects.

ETH elevates cGMP in 27/704 cells of ventral ganglia via multiple downstream pathways. In *Manduca* larvae, ETH action on the brain/SG and subsequent central release of EH within ventral ganglia apparently elicits cGMP elevation in the 27/704 cells of AG1–7 (Gammie and Truman, 1999; Zitnan and Adams, 2000). Intracellular recordings showed that either epitracheal gland extracts or synthetic ETH elicits increased electrical activity in the brain VM neurons *in vitro* within 4–13 min. Individually isolated VM somata also show increased excitability within 10 min of ETH exposure (Ewer *et al.*, 1997; Gammie and Truman, 1999). These data suggest that ETH is acting directly on VM cells to cause EH release, while hemolymph-borne EH then acts back to elicit cGMP elevation in Inka cells and ETH release in a positive feedback loop (Ewer *et al.*, 1997). Thus, VM neurons appear to be one of the primary targets for ETH. *In situ* hybridization and calcium imaging studies indicate that VM cell bodies express the ETH receptor subtype A (ETHR-A; Cho, Kim and Adams, unpublished data). However, ETH receptors are expressed in a large number of additional neurons located in the

brain and ventral ganglia and ETH action on the debrained larval nerve cord lacking VM cell bodies results in normal cGMP elevation and ecdysis bursts as observed in the control intact CNS (Zitnan and Adams, 2000). Moreover, EH action on the desheathed SG and TG1–3 causes strong cGMP elevation in all intact (non-desheathed) abdominal ganglia and, conversely, EH treatment of the desheathed abdominal ganglia results in increased cGMP production in intact SG and TG1–3 (Zitnan and Adams, 2000). These data indicate that EH probably participates with other neuropeptides or amines in the activation of the cGMP network in *Manduca*.

Central release of CCAP and MIPs from IN-704 appears to provide the necessary signaling for immediate initiation of ecdysis behavior. Immunohistochemical and *in situ* hybridization studies show that IN-704 produce CCAP and MIPs, whereas neurosecretory cells 27 produce only CCAP (**Figure 9d**; Ewer and Truman, 1996; Loi *et al*., 2001; Davis *et al*., 2003; Spalovska-Valachova and Zitnan, unpublished data). The central release of these neuropeptides during larval ecdyses of *Manduca* is indicated by decreased immunohistochemical staining with antisera to CCAP and MIP (Gammie and Truman, 1997a; Davis *et al*., 2003). Furthermore, application of synthetic CCAP on the isolated, desheathed chain of abdominal ganglia AG1–8 induces the ecdysis motor program (Gammie and Truman, 1999; Zitnan and Adams, 2000). However, CCAP only causes occasional nonpatterned bursts when applied on the entire desheathed CNS. On the other hand, application of a mixture of CCAP and MIPs induces in these nerve cords typical ecdysis bursts in just a few minutes. MIPs apparently suppress activity of pre-ecdysis neurons, while CCAP controls activity of the ecdysis network (Zitnan and Adams, unpublished data).

During pupal and adult ecdyses, only cells 27 show cGMP, elevation, indicating that CCAP and MIP release from IN-704 does not require cGMP, at least in these stages (Ewer and Truman, 1997). Genetically programmed cell death eliminates the entire 27/704 network within 36 h after adult moth eclosion (Ewer *et al*., 1998).

3.1.6.1.4. Inhibition from anterior ganglia delays ecdysis onset Ecdysis behavior in *Manduca* requires ETH activation of centers in the brain and subesophageal ganglion, from which descending inputs to the ventral nerve cord activate ecdysis neuronal circuitry (Novicki and Weeks, 1996; Zitnan and Adams, 2000). During the natural ecdysis sequence in *Manduca*, activation of ecdysis circuitry is complete about 30 min after the start of pre-ecdysis, but ecdysis is initiated some 30 min later. In ETH injected animals, activation of ecdysis circuitry is already complete 10–15 min into pre-ecdysis, well before initiation of ecdysis behavior some 30 min later. Once ecdysis circuitry is activated, the continued presence of ETH is not necessary for ecdysis initiation, indicating that ETH is a "triggering" peptide that sets in motion a sequence of events culminating in ecdysis.

The delay ($\sim$30 min) between ETH activation of the ecdysis network and initiation of behavior is controlled by a balance of excitation and inhibition from cephalic and thoracic ganglia. Evidence for this comes from experiments showing that ligations posterior to the head or thorax or brief CO_2 exposure considerably accelerates the onset of ecdysis during larval, pupal, and adult ecdyses (Zitnan and Adams, 2000; Fuse and Truman, 2002; **Figure 21**). These experiments indicate that descending inhibitory input from the SG and TG1–3 delays the central release of CCAP and MIPs from the 27/704 network in AG1–7. An independent clock in each abdominal ganglion controls the timing of disinhibition, allowing animals to switch from pre-ecdysis to ecdysis behavior.

After the old cuticle is completely shed, animals immediately stop ecdysis behavior. However, if the old cuticle cannot be shed, ecdysis contractions continue for a much longer time (up to 1–2 h). Similarly, isolated nerve cords lacking sensory connections to the cuticle show continuous ecdysis bursts for hours. These observations suggest that cessation of ecdysis behavior is controlled by sensory input from the cuticle, which probably re-activates inhibitory neurons to irreversibly stop the ecdysis motor program after shedding is completed.

Excitation and inhibition associated with initiation of ecdysis behavior appears to be related to sequential phases of cGMP elevation in different groups of central neurons. Six to eight hours prior to onset of pre-ecdysis, cGMP immunoreactivity (cGMP-IR) is detected in 27/704 neurons of the SG, TG1–3, but not in AG1–7 (Ewer and Truman, 1997; Zitnan and Adams, 2000). Following onset of pre-ecdysis, staining in the SG and TG1–3 gradually increases. At 30 min into pre-ecdysis, cGMP staining in 27/704 neurons of AG1–7 appears and increases in intensity over the next 15 min. At this time, additional neurosecretory cells ($L_{2,5}$) show weaker cGMP-IR in each AG1–7 (Zitnan and Adams, 2000; Fuse and Truman, 2002). It appears that cGMP elevation in AG1–7 neurons coincides with activation of ecdysis circuitry, since ligations and removal of the head or thorax at this time accelerates initiation of ecdysis behavior. In ETH injected

larvae, cGMP is elevated in 27/704 neurons of AG1–7 after 10–15 min. Surgery or ligations applied after this time accelerate initiation of ecdysis behavior, whereas their application before this time prevents ecdysis. Similar, but less obvious, results are obtained from measurements of behavior in ETH treated, isolated nerve cords (Zitnan and Adams, 2000).

3.1.6.1.5. Motoneurons controlling ecdysis behaviors Electrophysiological and cobalt backfilling techniques were used to identify motoneurons controlling muscle contractions during larval and pupal ecdysis behaviors of *Manduca* (Weeks and Truman, 1984a,b). These motoneurons innervate specific muscles of the body wall or prolegs and control their contractions during ecdysis behavior (Taylor and Truman, 1974; Levine and Truman, 1982, 1983; Weeks and Truman, 1984a, 1984b). For example, peristaltic contractions of intersegmental muscles are regulated by medial ISM motoneurons, which exit through dorsal nerves of the next posterior ganglion. Proleg retractions at larval ecdysis are controlled by principal and accessory planta retractor muscles innervated by the posteriolateral PPR and APR motoneurons, respectively. Interestingly, these neurons retain their activity even if prolegs degenerate at pupation (Weeks and Truman, 1984b). Dorsoventral contractions of tergopleural muscles during peristaltic movements are controlled by contralateral motoneurons 2 and 3 (MN-2 and MN-3), which also control synchronous compressions during pre-ecdysis I behavior (Weeks and Truman, 1984a). The disparate burst patterns of MN2,3 during pre-ecdysis I and ecdysis may reflect a switch in interneuron input. The IN-402 interneurons are necessary for synchronous bursts of MN2,3 during pre-ecdysis I (see Section 3.1.6.1), but interneurons controlling activity of MN2,3 during peristaltic movements are unknown. Alternatively, release of different upstream peptides could cause changes in the network properties driving these motor neurons.

3.1.6.1.6. Natural and ETH-induced pupal and adult behaviors Morphological markers useful for determination of time to pupal ecdysis have been reported in pharate pupae (Truman, 1985; Zitnanova *et al*., 2001) and are summarized in **Table 1**. The ecdysis behavioral sequence during pupation was described *in vivo* and *in vitro* (Weeks and Truman, 1984a; Truman, 1985; Zitnan *et al*., 1996). Pre-ecdysis of pharate pupae always occurs with the animal positioned ventral side down, and is visible as weak rhythmic contractions of the abdomen. Although these contractions are often difficult to discern visually, blood pressure measurements revealed clear rhythmic pulses during pre-ecdysis (Zitnan *et al*., 1996). Robust ecdysis peristaltic contractions begin approximately 1 h later in the most posterior abdominal segment and move anteriorly. After rupture of the old cuticle along the dorsal thoracic midline, animals turn ventral side up and with the aid of strong peristaltic movements the cuticle is shed. During postecdysis, the proboscis, wing pads, and legs of the fresh pupa are then expanded and sclerotized to their typical shapes.

PETH injection has either no effect or causes weak rhythmic contractions likely representing pre-ecdysis in animals injected 3–4 h prior to ecdysis. ETH treatment 3–48 h prior to natural ecdysis induces ecdysis behavior within 35–60 min; weak pre-ecdysis behavior preceding ecdysis is only observed in pharate pupae injected 3–4 h prior to natural ecdysis. Removal of the head and thorax or CO_2 treatment during pre-ecdysis accelerates the onset of ecdysis behavior as observed in larvae (Zitnan and Adams, 2000; Fuse and Truman, 2002). ETH also induces strong ecdysis bursts in dorsal nerves of the isolated nerve cord *in vitro* (Zitnan *et al*., 1996).

Adult ecdysis (eclosion) behaviors are quite different from larval and pupal ecdysis and are composed of pre-eclosion and eclosion behaviors, as well as digging from the underground pupation site (Reynolds *et al*., 1979; Mesce and Truman, 1988). Pre-eclosion behavior is initiated by occasional rotations of the abdomen, which may be missing in some animals. The onset of eclosion behavior is characterized by strong movements of wing bases to break anterior parts of the pupal cuticle while abdominal retractions and extensions help the adult to emerge from the pupal case and to escape to the surface.

Pharate adults are sensitive to ETH beginning about 24 h prior to natural eclosion. ETH injections during this time period induce occasional abdominal rotations within 3–10 min, followed by a relatively quiescent phase. Eclosion behavior is initiated 2–3 h after ETH treatment and adults emerge in 10–20 min, but are usually wet and do not completely spread their wings (Zitnan *et al*., 1996). However, animals nevertheless climb to a suitable perch and assume the posture normally associated with wing expansion. This suggests that ETH may also be responsible for posteclosion behavior. Similar to pharate larvae and pupae, decapitation or CO_2 treatment considerably accelerates eclosion onset (Mesce and Truman, 1988; Ewer *et al*., 1997; Fuse and Truman, 2002). Interestingly, adults retain the larval ecdysis motor program. Typical larval-like peristaltic abdominal movements can be induced in eclosing pharate adults by transecting connectives

between the pterothoracic and abdominal ganglia (Mesce and Truman, 1988).

Since ETH-AP is processed from the ETH precursor and released at ecdysis (Zitnan *et al*., 1999), its function was tested by injection in parallel with PETH and ETH. However, no obvious effects were observed following injections of ETH-AP into pharate larvae, pupae, or adults and the isolated larval CNS shows no specific response to ETH-AP treatment *in vitro* (Zitnan *et al*., 1999; Zitnan, unpublished observations).

3.1.6.2. Natural and Peptide-Induced Behaviors in *Bombyx*

3.1.6.2.1. Larval pre-ecdysis and ecdysis Developmental markers and behavioral sequences during larval and pupal ecdyses and adult eclosion have been described recently (Zitnan *et al*., 2002) (see Table 2). Natural larval behavior is initiated by pre-ecdysis composed of asynchronous dorsoventral, ventral, and posteriolateral body wall contractions, plus leg and proleg retractions. After about 1 h of pre-ecdysis contractions, larvae switch to anteriorly directed peristaltic movements (ecdysis behavior), which result in shedding of the old cuticle in 10–12 min (Figure 22).

Comparisons of *Manduca* pre-ecdysis and ecdysis behaviors with those in *Bombyx* revealed substantial differences. For instance, *Bombyx* pre-ecdysis I and pre-ecdysis II are not synchronized and body wall or proleg contractions can occur randomly on the left or right side of any segment (Zitnan and Adams, 2000). Ligation and transection experiments of *Bombyx* larvae *in vivo* and *in vitro* confirmed that each ganglion contains the entire circuitry for pre-ecdysis I and II, and that connections to the TAG or other distal ganglia are not necessary for generation of these motor patterns. This indicates that IN-402 necessary for synchronous pre-ecdysis I contractions in *Manduca* is probably missing or are not activated in *Bombyx*. Thus pre-ecdysis contractions in *Bombyx* and *Manduca* are quite different, while ecdysis movements are very similar in both species.

Table 2 Timelines of morphological markers in *Bombyx mori*

Time before ecdysis	*Morphological marker*
Pharate 5th instar larva	
28 h	Head capsule slip (HCS)
15–16 h	Edges of new light yellow spiracles show gray pigmentation
12 h	Edges of new spiracles turn black
5 h	Remaining lighter areas of spiracles darken to a brown–black color
Pharate pupa	
24 h	Pharate pupae stop spinning the cocoon
4 h	Shrinking of the old larval cuticle between all thoracic and abdominal segments
Pharate adult	
6–7 days	Yellow–brown pigmentation of eyes
5–6 days	Black pigmentation of eyes
1–2 days	Dark pigmentation of lines on the wings

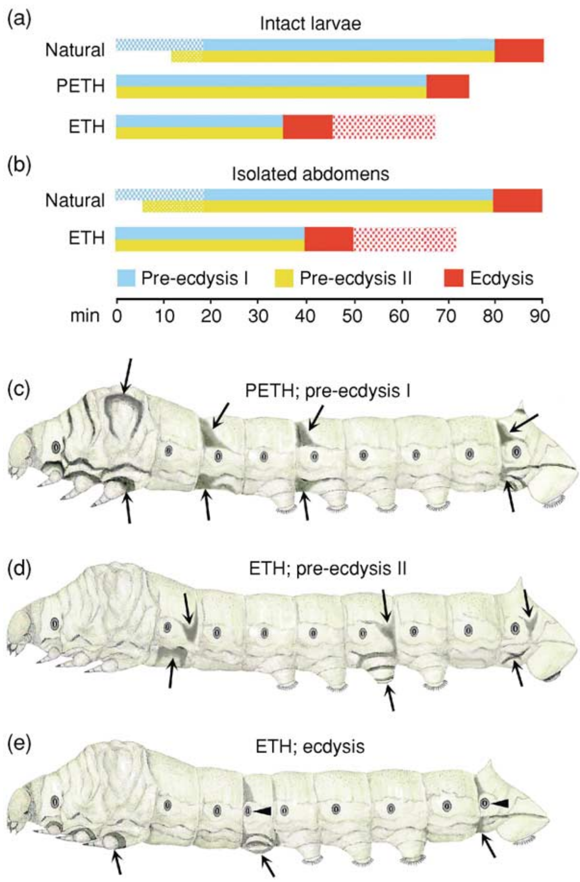

Figure 22 The ecdysis sequence of *Bombyx* pharate larvae. (a) Timelines showing duration of natural and peptide-induced pre-ecdysis and ecdysis in intact pharate larvae. Note that injection of PETH or ETH (50 pmol) induces the entire sequence and ecdysis onset is accelerated when compared with natural behavior. ETH is more effective than PETH and most larvae injected with ETH continue to show ecdysis contractions for up to 30 min (stippled line). (b) Time of the initiation and duration of natural and ETH-induced ecdysis sequences are very similar in isolated abdomens compared with intact pharate larvae of the same stage. (c) PETH-induced asynchronous dorsoventral and leg contractions in thorax and abdomen (pre-ecdysis I, arrows pointing at shaded areas indicate locations of muscle insertions and direction of muscle contractions). (d) Subsequent ETH injection induces asynchronous ventral, posteriolateral, and proleg contractions (pre-ecdysis II, shaded areas, arrows). (e) These animals then switch to anteriorly directed peristaltic contractions accompanied by proleg retractions (ecdysis, shaded areas, arrowheads). (Data from Zitnan, D., Hollar, L., Spalovska, I., Takac, P., Zitnanova, I., *et al*., **2002**. Molecular cloning and function of ecdysis-triggering hormones in the silkworm *Bombyx mori*. *J. Exp. Biol. 205* (Pt 22), 3459–3473.)

Peptide-induced behaviors in *Bombyx* can also differ substantially from those induced in *Manduca*. For example, injection of either PETH or ETH into pharate *Bombyx* larvae (10–15 h prior to ecdysis) induces both pre-ecdysis and ecdysis behaviors *in vivo*. Likewise, peptide treatments of the isolated CNS *in vitro* elicit corresponding burst patterns (Figure 23). On the other hand, injections of pharate *Bombyx* larvae 1 day prior to expected ecdysis elicit responses similar to those induced in *Manduca*: PETH elicits only pre-ecdysis I, whereas ETH induces the entire sequence. These data indicate that CNS sensitivity to PETH and ETH becomes progressively stronger as animals approach the onset of natural ecdysis behavior (Zitnan *et al*., 2002).

Peptide-induced behaviors in *Bombyx* differ from those observed in *Manduca* in another notable way. Injection of isolated abdomens with ETH elicits the entire ecdysis behavioral sequence associated with normal elevation of cGMP in abdominal ganglia, but no detectable release of EH. This means that, in *Bombyx*, descending input from the brain to abdominal ganglia is not required for activation of ecdysis circuitry as was observed in *Manduca*. Finally, although ETH-AP has no detectable behavioral action in *Manduca*, *Bombyx* larvae respond with nonsynchronized proleg and ventral contractions resembling pre-ecdysis II (Zitnan *et al*., 2002).

3.1.6.2.2. Pupal ecdysis and adult eclosion In contrast to *Manduca* (see Section 3.1.5.1), *Bombyx* pharate pupae show well-defined and pronounced pre-ecdysis behavior composed of dorsoventral, leg, and proleg contractions for about 1–1.5 h and then switch to robust ecdysis peristaltic movements (Figure 24). During anteriorly directed ecdysis contractions, larval cuticle of the head capsule and thorax is ruptured along the dorsal line, and the entire old cuticle is shed with attached larval foregut, hindgut, and tracheae in 10–12 min. As described in pharate larvae, injections of either PETH or ETH elicit the entire behavioral sequence (Figure 24). ETH-AP treatment induced weaker proleg and ventral contractions for about 1 h followed by weak and occasional ecdysis movements for up to 1 h. Isolated abdomens show natural pre-ecdysis and ecdysis at the expected time and both behaviors could be induced prematurely by ETH injection (Figure 24).

The natural eclosion behavioral sequence of pharate adults consists of three distinct phases: rotations of the abdomen, a quiescent phase, and eclosion contractions (Figure 25). During peristaltic movements of the abdomen associated with eclosion, adults partially emerge from the pupal cuticle and, after dissolving the cocoon around the head with a salivary secretion containing cocoonase, they escape and spread their wings. Injection of PETH or ETH induces in most pharate adults the entire behavioral sequence. The importance of the brain in ecdysis activation was demonstrated by surgical experiments. Decapitated or brain-extirpated pharate adults never eclose and ETH fails to induce eclosion behavior in these animals (Zitnan *et al*., 2002). In summary, these data showed that both PETH and ETH induce the entire behavioral sequence, although

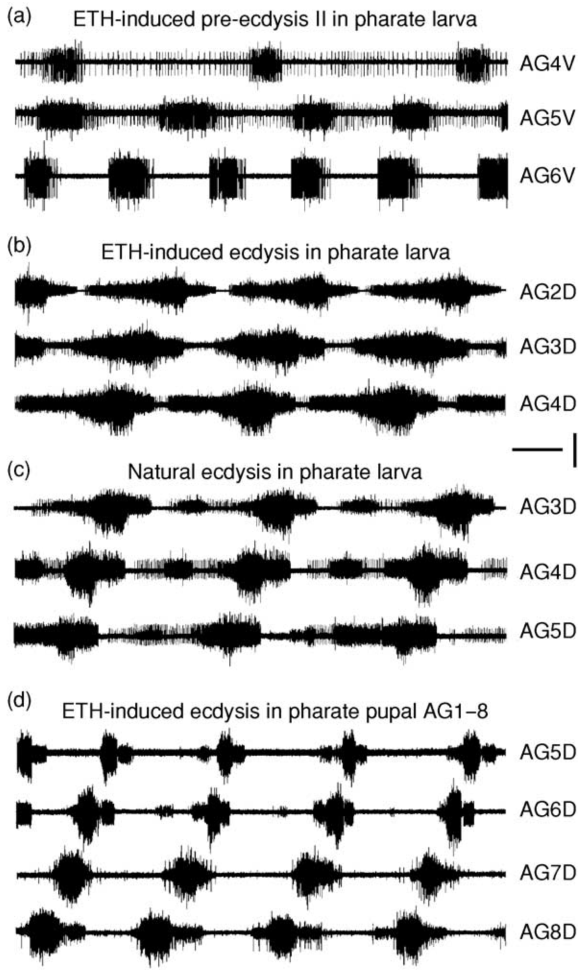

Figure 23 Pre-ecdysis and ecdysis burst patterns recorded in the isolated CNS of *Bombyx* pharate larvae and pharate pupae *in vitro*. (a, b) ETH-induced pre-ecdysis II and ecdysis in the entire CNS of pharate 5th instar larvae. (a) Note asynchronous pre-ecdysis II bursts in ventral nerves of abdominal ganglia 4–6 (AG4-6V). (b) ETH-induced ecdysis bursts in dorsal nerves of abdominal ganglia 2–5 (AG2-5D). These burst patterns are very similar to natural ecdysis bursts (c). (d) ETH-induced ecdysis bursts in dorsal nerves of the isolated chain of abdominal ganglia (AG1–8) of pharate pupa. Ecdysis burst pattens in intact CNS are very similar (not shown). Calibration bars: horizontal 5 s, vertical 10 μV. (Modified from Zitnan, D., Hollar, L., Spalovska, I., Takac, P., Zitnanova, I., *et al*., **2002**. Molecular cloning and function of ecdysis-triggering hormones in the silkworm *Bombyx mori*. *J. Exp. Biol.* *205* (Pt 22), 3459–3473.)

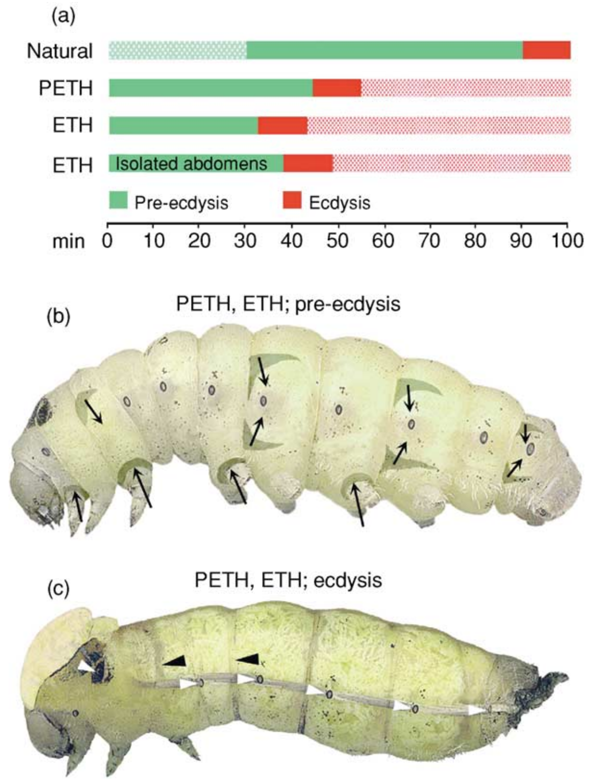

Figure 24 The ecdysis sequence of *Bombyx* pharate pupae. (a) Timelines showing duration of the natural and peptide induced ecdysis sequences. Stippled green line during the first 30 min of pre-ecdysis indicates initial weak and occasional dorsoventral contractions, which become gradually stronger. PETH or ETH injections induce the entire ecdysis sequence in intact animals and isolated abdomens. Early pharate pupae are not able to shed their old cuticle, thus ecdysis contractions last for up to 1 h (stippled red lines). (b) Shaded areas indicate dorsoventral, leg, and proleg contractions during pre-ecdysis induced by PETH or ETH injection. (c) Pre-ecdysis is later replaced by strong ecdysis peristaltic movements (black arrowheads), which result in rupture and shedding of the larval cuticle and tracheae (white arrowheads). (Data from Zitnan, D., Hollar, L., Spalovska, I., Takac, P., Zitnanova, I., *et al.*, **2002**. Molecular cloning and function of ecdysis-triggering hormones in the silkworm *Bombyx mori*. *J. Exp. Biol. 205* (Pt 22), 3459–3473.)

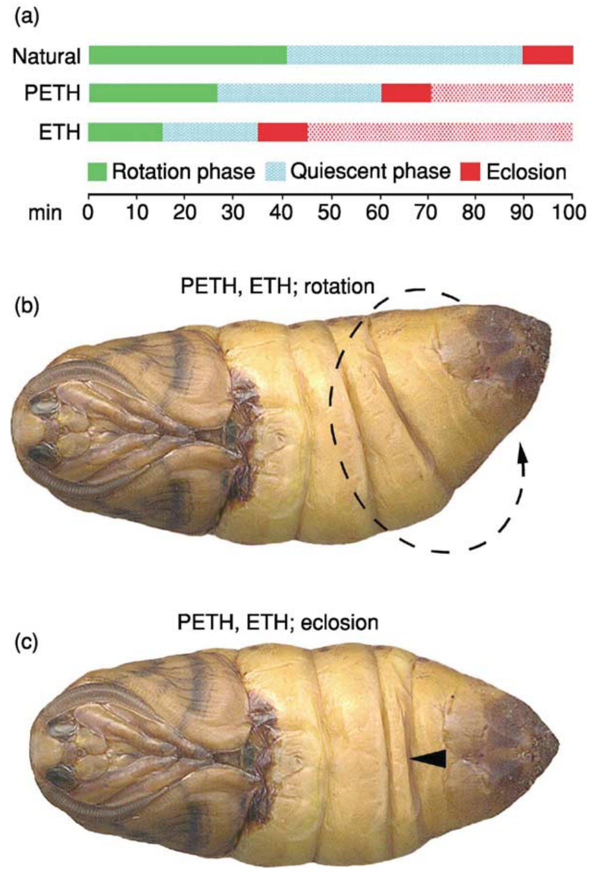

Figure 25 The eclosion sequence of *Bombyx* pharate adult. (a) Timelines showing rotation, quiescent, and eclosion behavioral phases during natural and peptide induced eclosion sequence. Animals injected with PETH or ETH show accelerated response compared to that expressed during natural eclosion. Since peptide injected animals fail to escape from the pupal cuticle, eclosion contractions last for up to 1 h. (b) Both PETH and ETH elicit vigorous rotations of the abdomen (arrow), interrupted by short quiet intervals. (c) After a prolonged quiescent phase, the animal initiates eclosion peristaltic contractions of abdominal segments (arrowhead). (Data from Zitnan, D., Hollar, L., Spalovska, I., Takac, P., Zitnanova, I., *et al.*, **2002**. Molecular cloning and function of ecdysis-triggering hormones in the silkworm *Bombyx mori*. *J. Exp. Biol. 205* (Pt 22), 3459–3473.)

latencies for the onset of ecdysis or eclosion movements by PETH were more variable and generally longer than for ETH.

3.1.6.3. Natural and Peptide-Induced Behaviors in *Drosophila*

3.1.6.3.1. Larval and pupal ecdyses The first detailed study of larval ecdysis in *Drosophila* described morphological markers and a series of stereotypic physiological and behavioral events preceding the transition from first to second instar (Park *et al.*, 2002a). About 60 min in advance of ecdysis, a new set of mouthparts for the second instar become visible adjacent to those of the first instar, leading to the appearance of "double mouth hooks." The appearance of "double vertical plates" (dVP) 30 min later was used as a reference point, or "time zero" in the ecdysis sequence (Figure 26).

Using a transgenic fly line in which the nucleotide sequence of enhanced green fluorescent protein (*egfp*) was fused to the 3-prime end of the *eth* gene, release of ETH from Inka cells was observed as a loss of fluorescence shortly after dVP. Upon ETH release, old tracheae collapse and the new second instar tracheae are inflated. This occurs 10 min after dVP. About 5 min later, pre-ecdysis begins with a series of "anterior–posterior" (A–P) contractions. Five min later this leads to another

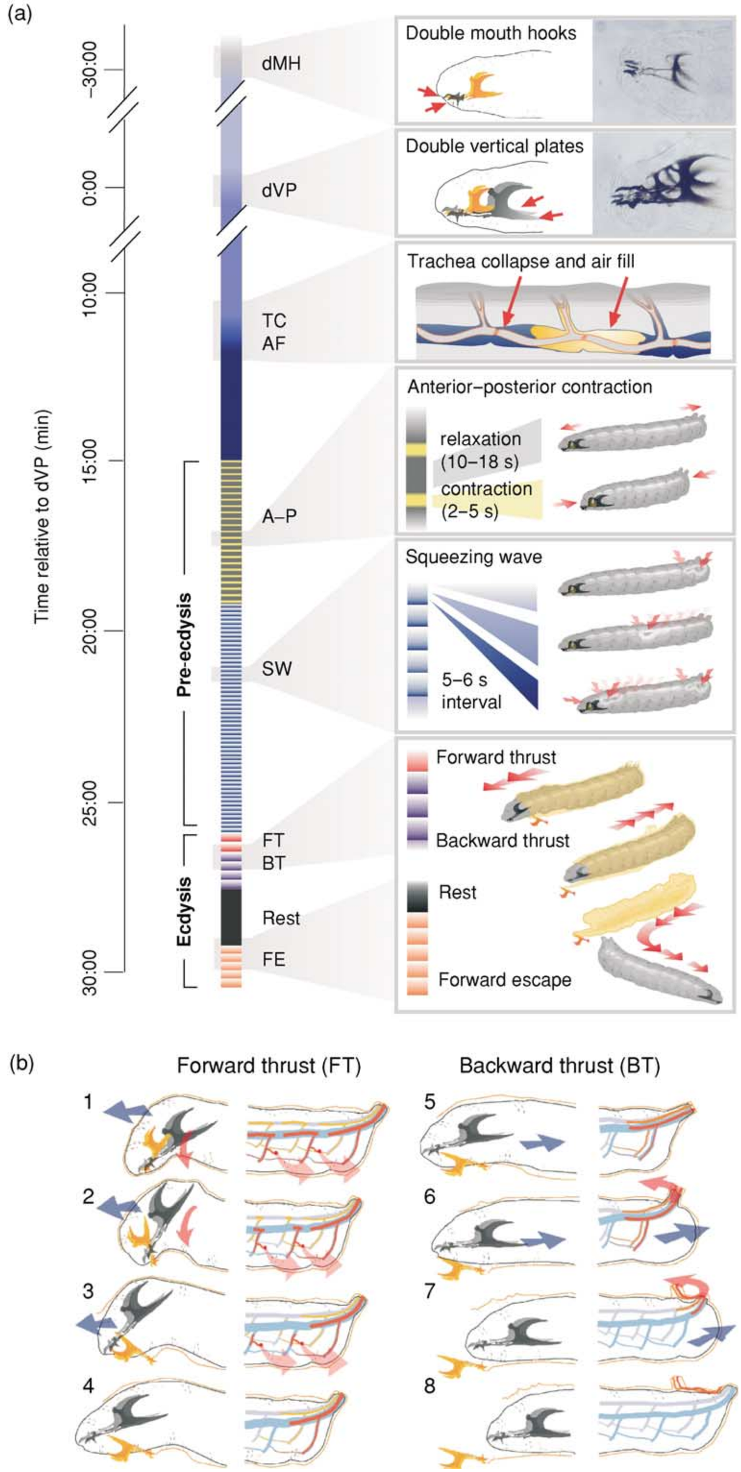

Figure 26 Timelines of the *Drosophila* ecdysis sequence. (a) About 60 min prior to ecdysis, a new set of mouth hooks for the 2nd instar larva becomes visible adjacent to those of the 1st instar ''double mouth hooks'' (dMH). The appearance of ''double vertical plates'' (dVP) 30 min later was used as ''time zero'' in the ecdysis sequence. Upon ETH release from Inka cells 10 min after dVP, old tracheae collapse and the new, 2nd instar tracheae are inflated. (a,b) About 5 min later, pre-ecdysis begins with a series of ''anterior–posterior'' (A–P) contractions followed by a different pattern of muscle contractions ''squeezing waves'' (SW). During A–P and SW pre-ecdysis movements, old and new mouthparts are separated. About 25 min after dVP, ecdysis behavior is initiated with one or two forward head thrusts (FT). These movements help to plant old mouthparts onto the substrate and to extricate old tracheae through lateral segmental spiracular pits, which are normally closed but become functional during ecdysis. Following backward thrust (BT) detaches and extricates remaining old posterior spiracles and tracheal linings out through the new spiracles. Ecdysis is completed following forward escape (FE) and turning movements. (Data from Park, Y., Filippov, V., Gill, S.S., Adams, M.E., **2002a**. Deletion of the ecdysis-triggering hormone gene leads to lethal ecdysis deficiency. *Development 129* (2), 493–503.)

pattern of muscle contractions referred to as "squeezing waves" (SW). During A-P and SW pre-ecdysis behaviors, vigorous muscle contractions are observed to pull the mouthparts alternately in anterior and posterior directions. These movements may be critical to the separation of old from new mouthparts during subsequent ecdysis behavior.

Ecdysis is initiated around 20 min after dVP. It begins with one or two forward head thrusts, whereby old mouth hooks and vertical plates are detached from the new and planted onto the surface of the substrate. The forward thrust also detaches and extricates parts of the old tracheal system through lateral segmental spiracular pits, which are normally closed but become functional during ecdysis. Subsequent backward thrust detaches the old from the new posterior spiracles and pulls the remaining old tracheal linings out through the new spiracles (**Figure 26**). Ecdysis is completed after forward and turning movements help the larva to escape from the old cuticle. The sequence of events leading up to ecdysis from 2nd to 3rd instar follows a very similar pattern. The only difference is that the appearance of double mouth hooks occurs considerably sooner (104 min before dVP) as compared to the first ecdysis (30 min before dVP).

A detailed description of morphological markers and behaviors during metamorphosis was published by Bainbridge and Bownes (1981). These authors identified numerous stages from wandering larva to adult subdivided to 52 distinct events, but here the focus is on markers and behaviors associated with pupal ecdysis, which is usually described as "head eversion" behavior (Zdarek and Friedman, 1986; Ward *et al*., 2003). We consider formation of a white puparium as the reference point or time zero. A gas bubble becomes visible in the dorsal part of the abdomen 3 h later and apolysis of larval and pupal cuticles is initiated at 4–6 h. This stage is called "cryptocephalic pupa." Major lateral tracheal trunks are obscured at 6.5–8 h followed by initiation of dorsomedial abdominal contractions at about 10–12 h. The abdominal bubble disappears at 12 h, while another bubble appears in the posterior part of the puparium and gradually moves anteriorly. As the gas bubble is displaced in the anterior portion of the puparium at about 12–13 h, pupal pre-ecdysis is initiated. It is characterized by rhythmic retractions of the animal from the puparium, which last for about 9–10 min (Park *et al*., 2003b). Subsequent ecdysis behavior is indicated by peristaltic body contractions for only 1 min associated with head eversion, extension of pupal legs and wing pads posteriorly along the abdomen, and shedding of the larval tracheae. Regular weak postecdysis contractions continuing for about 2 h may assist the pupa in achieving its final shape (Park *et al*., 2003b). This stage is named "phanerocephalic pupa."

3.1.6.3.2. Adult eclosion Timelines of the eclosion sequence and morphological markers useful in predicting ecdysis events in *Drosophila* pharate adults have been described (Kimura and Truman, 1990; McNabb *et al*., 1997; Park *et al*., 1999). Resorption of molting fluid is initiated about 6–7 h before expected eclosion. The pupal cuticle then passes through a series of changes in appearance referred to as smooth (S), smooth/grainy (S/G), grainy (G), and finally white (W). Certain steps differ in duration between males and females, namely that the smooth stage lasts for ~5.5 h before females' transition to the smooth/grainy stage, whereas males show the smooth stage for only a matter of minutes before advancing to the smooth/grainy stage. Commencement of the white stage (W) occurs upon inflation of the head tracheal sacs and indicates that pre-eclosion behavior has been initiated.

Pre-eclosion starts about 1 h prior to eclosion and is composed of dorsoventral contractions of the first abdominal tergum and ptilinium extension resulting in inflation/expansion and tracheal filling of the head (W). Pre-eclosion is followed by a quiescent period, but the entire behavior may be absent in up to 24% animals (Park *et al*., 1999). Eclosion behavior consists of four consecutive events, including head expansion to open the operculum, forward head thrusts, lateral thoracic contractions, and forward peristaltic abdominal contractions helping the fly to emerge from puparium. Interestingly, neck ligation of pharate adults during pre-eclosion (extended ptilinum stage) causes immediate onset of ecdysis (Baker *et al*., 1999). This indicates that inhibitory neurons and factor(s) in the cephalic ganglia delay the initiation of ecdysis, similar to that observed in *Manduca* (Ewer *et al*., 1997; Zitnan and Adams, 2000; Fuse and Truman, 2002).

3.1.6.3.3. Role of ETH in larval and adult ecdyses Premature injection of ETH1 accelerates all the events shown in **Figure 27** including tracheal inflation, anterior–posterior contractions, squeezing waves, and ecdysis behavior. Injection of the peptide (≥0.1 fmol) into *Drosophila* larvae at the double mouth hook stage induces in 3–4 min old tracheal collapse and air inflation of new tracheae, followed by a complete set of pre-ecdysis and ecdysis behaviors. ETH2 also induces tracheal and behavioral responses, but higher concentrations are needed (≥1 fmol for tracheal dynamics; ≥10 fmol for ecdysis behavior) and pre-ecdysis behaviors are absent. After a quiescent stage

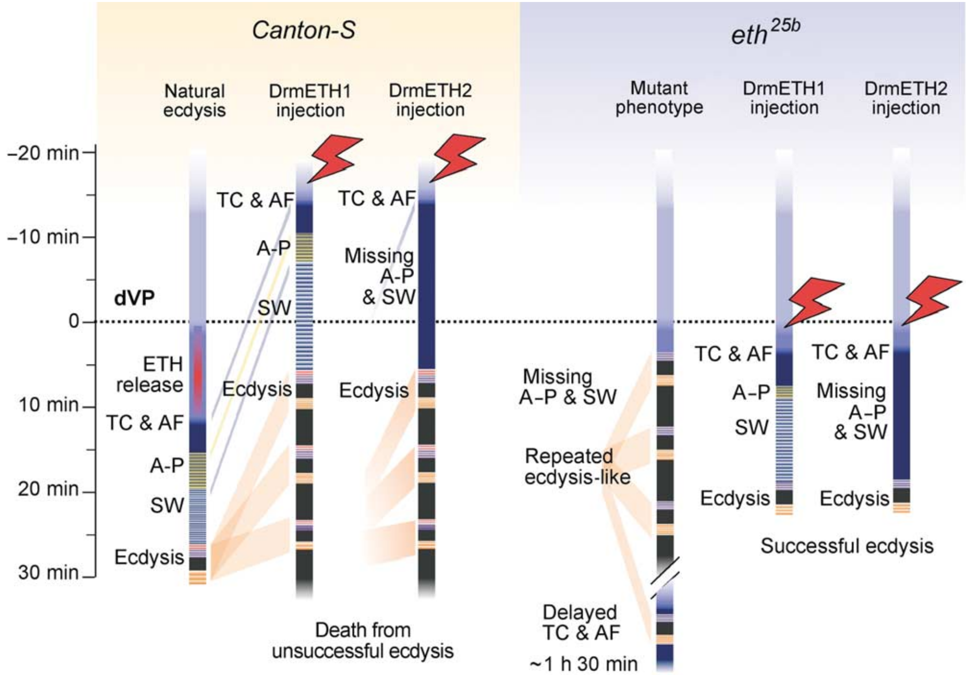

Figure 27 Time lines depicting the ecdysis sequence in wild-type Canton S and in the *eth* deletion mutant line *eth*^{25b}. During natural ecdysis, ETH release begins shortly after double vertical plates (dVP), followed by collapse of old tracheal tubes (TC) and air inflation (AF) of new, pre-ecdysis consisting of anterior–posterior (AC) contractions and squeezing waves (SW), and finally ecdysis. Premature DrmETH1 injection accelerates all events that normally follow natural ETH release, but DrmETH2 elicits only accelerated tracheal dynamics and ecdysis. When ETH1 or ETH2 is injected prematurely, ecdysis behavior ensues but is unsuccessful due to failure to separate old and new mouth hooks and vertical plates. The mutant phenotype *eth*^{25b} exhibits delayed tracheal dynamics, fails to perform pre-ecdysis and normal ecdysis behaviors, and shows high mortality (>98%) at the first larval ecdysis. Injection of ETH1 or ETH2 at the dVP stage reverses the mortality observed in this mutant phenotype. (Data from Park, Y., Filippov, V., Gill, S.S., Adams, M.E., **2002a**. Deletion of the ecdysis-triggering hormone gene leads to lethal ecdysis deficiency. *Development 129* (2), 493–503.)

following tracheal inflation, animals initiate ecdysis behavior (Park *et al.*, 2002a). These studies illuminated a previously unrecognized role for ETH in eliciting tracheal dynamics, although it is likely that ETH acts through downstream signals on the tracheal system. As described in *Drosophila* larvae, injections of ETHs into pharate adults accelerate the onset of pre-eclosion and eclosion behaviors, and, again, ETH1 is more effective than ETH2 (Park *et al.*, 1999). Injection of *Manduca* ETH also induces the entire behavioral sequence (McNabb *et al.*, 1997; Baker *et al.*, 1999; Park *et al.*, 1999), but animals injected with PETH show no response.

Whether ETH is necessary for ecdysis depends on the ability to observe natural ecdysis in the absence of the peptide. To address this question, the gene *eth* encoding ETH1 and ETH2 was deleted by imprecise P-element excision (Park *et al.*, 2002a). To excise *eth*, a fly line having a P-element insertion 1427 bp downstream of the gene was obtained. The P-element was mobilized by crossing this line with the Δ2–3 transposase line. Deletion of *eth* resulted in lethal behavioral and physiological deficits. Homozygous null mutants (*eth*-) develop through embryogenesis and the first instar, but 98% die at the first larval ecdysis. These animals show considerable delays in tracheal collapse and air inflation, lack pre-ecdysis behavior, exhibit abnormal ecdysis behavior, and are unable to shed the old cuticle completely. Precisely timed injection of ETH1 restores both respiratory and behavioral defects and animals progress to the 2nd instar (**Figure 27**). The gene encoding ETH1 therefore plays an obligatory role in the regulation of ecdysis, and the absence of ETHs leads to defects in air filling of the tracheal system, unsuccessful ecdysis and lethality (Park *et al.*, 2002a).

3.1.6.3.4. Roles for EH in ecdysis There is a good deal of evidence generated from studies of EH in *Manduca* (Truman, 1992), *Bombyx* (Kono *et al.*, 1990b), and *Heliothis virescens* (Kataoka *et al.*, 1987) that EH is sufficient to trigger pre-ecdysis and ecdysis behaviors. In the first study to test for the necessity of EH in eclosion, the cell-specific promoter of the EH gene in *Drosophila* was used to drive the cell death genes *reaper* and *head involution defective* to kill EH synthesizing cells (McNabb

et al., 1997). In spite of EH cell ablation, ~50% of developing flies reached the puparium stage, and ~80% of these successfully performed eclosion.

Nevertheless, several defects in the coordination of eclosion-related events are evident in flies. First, tracheal inflation is delayed. Second, while bouts of head expansion, head thrusts, thoracic contractions, and abdominal contractions that comprise eclosion behavior are synchronized and alternate with quiescent periods in wild-type flies, they are disorganized and performed continuously with no quiescent periods in EH-KO flies. Furthermore, eclosion behaviors are weaker in the EH-KO flies and thus the entire eclosion sequence is prolonged. Finally, two-thirds of the mutant flies failed to undergo normal posteclosion expansion of wings and hardening of the adult cuticle.

These observations indicate that, despite the ability of flies to undergo larval, pupal, and adult ecdysis behaviors, they fail to perform many of the steps on schedule and in a coordinated fashion. Nevertheless, it is remarkable that almost one-half of the mutant fly population survives to the adult stage in the absence of EH. This study indicates that, while EH is involved in regulation of ecdysis and eclosion, it has a nonessential role in these processes (McNabb *et al.*, 1997).

Other interesting outcomes emerged from the study of EH-KO flies. First, based on Truman's original discoveries of EH activity in giant silkmoths, it has been assumed that EH is involved in the circadian gating of adult eclosion (Truman and Riddiford, 1974). Second, EH has been associated for many years with programed cell death of larval abdominal body wall muscles during metamorphosis (Schwartz and Truman, 1984). However, studies of EH-KO flies demonstrated both a normal free-running circadian rhythm of eclosion as well as programed cell death of intersegmental muscles (McNabb *et al.*, 1997). Therefore, other hormonal signals are likely involved in these processes.

3.1.6.3.5. Role of CCAP in ecdysis In contrast to its likely essential role in *Manduca* ecdysis behavior (Gammie and Truman, 1997a, 1999; Zitnan and Adams, 2000), CCAP does not appear to be of central importance in *Drosophila* ecdysis (Park *et al.*, 2003b). Activation of ecdysis is associated with cGMP elevation in CCAP-producing neurons of diverse insects (Ewer and Truman, 1996), but elevation of cGMP in central neurons of *Drosophila* is completely absent during larval ecdyses. During adult eclosion, cGMP is restricted to small neurons in the SG (3–5 pairs) and AG (1–2 pairs), as well as in the tracheae associated with the CNS (Ewer and Truman, 1996; Baker *et al.*, 1999). Double staining confirmed that neurons producing cGMP during adult eclosion are clearly different from the segmentally distributed CCAP expressing cells (Ewer and Truman, 1996).

To investigate the possible functional role of CCAP in *Drosophila* ecdysis, CCAP neurons were killed using a *CCAP*-GAL4 driver to cause cell-selective expression of *reaper* (Park *et al.*, 2003b). Surprisingly, larval ecdysis and adult eclosion occurred normally and survival of mutant flies through the end of the last larval instar was indistinguishable from controls. Some subtle effects included increased duration of pre-ecdysis and ecdysis. During pupal ecdysis, pre-ecdysis behavior occurred on schedule, but the majority of animals died due to failure in head eversion. Since normal head eversion is associated with CCAP release, failure of this process in CCAP-KO flies confirms its necessary role for this process. Although the precise roles of CCAP in head eversion are not known, it is likely that dysfunction in the circulatory system regulated by this peptide may be to blame. A small number of animals survived to perform relatively normal adult eclosion. Some subtle quantitative differences in the length of time involved in tracheal air filling and reduced ability to expand the body were observed. This expansion is necessary for efficient propulsion of the animal forward during peristaltic ecdysis contractions.

Overall, the major defects in CCAP-KO flies were failure of head eversion at pupal ecdysis, and failure to expand and sclerotize the wings after adult eclosion. The latter observations implicate function of CCAP neurons either in the corelease of bursicon or in the activation of downstream bursicon neurons (see Section 3.1.6.6.2).

3.1.6.4. Hatching and Ecdysis of Locust Nymphs

Behavior and neurophysiology during hatching and the first ecdysis have been decribed in nymphs of *L. migratoria* and *S. gregaria* (Bernays, 1971, 1972b, 1972c; Truman *et al.*, 1996). Three behavioral phases are observed: (1) hatching behavior of undulatory vermiform larva with legs held close to the body in order to escape from the eggshell and dig through the soil to the surface; (2) ecdysis behavior initiated upon reaching the surface to shed the embryonic cuticle; and (3) expansional behavior to assume a posture and locomotory patterns typical of a hexapod nymph (Bernays, 1971, 1972a). Immunohistochemical techniques showed that the second phase of these behaviors (ecdysis) is associated with elevation of cGMP in a set of neurons producing CCAP. Hatching and digging animals do not produce cGMP in these neurons, but cGMP appears in

the CCAP neuronal network immediately before the free larva initiates ecdysis behavior associated with air swallowing and tracheal air filling (Truman *et al.*, 1996). The cGMP immunoreactivity (cGMP-IR) reaches a peak about 5 min after initiation of ecdysis and then gradually decreases. By 20 min, cGMP-IR is considerably reduced and disappears 10 min later. If the nymphs hatch under moist cheesecloth, they do not ecdyse but continue digging behavior. These larvae do not show cGMP elevation or only traces of cGMP-IR after 10–60 min of digging. However, when ecdysing nymphs with elevated cGMP levels are covered with moist cheesecloth, they resume digging. These "digging ecdysing larvae" produce cGMP in CCAP neurons for prolonged time, ranging from 40 to 100 min. Once ecdysed nymphs assume the hopper form, covering with cheesecloth does not result in the resumption of digging behavior and cGMP elevation. Hence, sensory input from the cuticle appears to be important in the initiation as well as cessation of the ecdysis behavior and associated cGMP production in CCAP neurons.

3.1.6.5. Adult Ecdysis of Crickets and Locusts

Detailed behavioral analysis and associated muscle contractions recorded by electromyography were described during adult ecdysis of the cricket *Teleogryllus oceanicus* (Carlson and Bentley, 1977; Carlson, 1977a, 1977b). These authors divided the entire ecdysis sequence into four phases: preparatory (2 h), ecdysial (20 h), expansional (1 h), and exuvial (30 min), which are composed of 48 identified motor programs. The preparatory phase corresponds to pre-ecdysis in other insects and consists of contractions of various muscles to loosen, anchor, and split the old cuticle. This phase is considered as pre-ecdysis to be consistent with observations in other insects. Cricket adult pre-ecdysis is initiated with grooming, locomotion, and pushups, later accompanied by synchronous longitudinal contractions of the abdomen to loosen and split the old cuticle along the dorsal ecdysial line. These synchronous abdominal contractions resemble pre-ecdysis I in *Manduca*. Other motor programs are later activated, e.g., alternating contractions of coxal muscles help to anchor the claws to the substrate and antennal beating and scissoring result in loosening the antennae. The onset of ecdysis behavior is preceded by a quiescent phase for 10 min. As in other insects, the cricket ecdysis behavior is characterized by anteriorly directed bouts of abdominal contractions and air swallowing. Additional motor programs are recruited later and involve either synchronous or alternating contractions of muscles in the head, thorax, or legs to extricate the entire body from the exuvium.

The postecdysis expansional phase includes rhythmic contractions of abdominal and leg muscles, as well as air swallowing to expand the cuticle of the body and appendages (legs and wings). After the new cuticle is expanded to its definitive shape, the expansional posture is abandoned and the cricket enters the exuvial phase, which comprises the eating of its shed cuticle (exuvium) accompanied by sporadic fluttering, spreading, and refolding of wings (Carlson, 1977a).

Removal of the old cuticle prior to onset of the ecdysis sequence results in delayed initiation of behaviors by 2 h. After this delay, normal pre-ecdysis and ecdysis behaviors are initated, but the animal becomes arrested at the first half of the ecdysis motor programs. When the old cuticle is peeled at ecdysis, the expansional and exuvial phases follow after some delay. These data show that ecdysis motor programs can be initiated without sensory input in *Teleogryllus*, but that sensory information from certain structures (e.g., cerci) is necessary for initiation, termination, or reactivation of some specific programs. For example, if cerci are peeled prior to the ecdysis sequence, animals never initiate pre-ecdysis and ecdysis behaviors, but show abdominal tetanic contractions characteristic for the post-ecdysis expansional phase. By comparison, *Manduca* larvae never initiate the ecdysis sequence if the old cuticle is peeled manually, but adults usually inflate their wings and abdomens after they are removed from the pupal cuticle several hours prior to expected eclosion (Miles and Booker, 1998; Zitnan, unpublished data).

The cephalic ganglia appear to be important for inhibiting the ecdysis peristaltic program in *Teleogryllus*. Removal of the head at any time during the behavioral sequence results in the initiation of ecdysis abdominal peristaltic movements in combination with the original behavior. For example, if animals are decapitated during pre-ecdysis, they continue to show pre-ecdysis synchronous longitudinal pumping alternating with peristaltic ecdysis contractions, while decapitation at the expansional phase results in a combination of tetanic and peristaltic contractions (Carlson, 1977a). In contrast, decapitation of *Manduca* and *Drosophila* suppresses pre-ecdysis within a few minutes and accelerates ecdysis onset (see Sections 3.1.6.1.4 and 3.1.6.3.2).

The desert locust, *S. gregaria*, displays similar behaviors during adult ecdysis as described in crickets. The locust ecdysis sequence has been divided into several stages consisting of pre-emergence (stages 1, 2), emergence (stages 3, 4), expansional (stage 5), and postexpansional (stage 6) behaviors

(Hughes, 1980a). The ecdysis sequence starts after the fully grown 5th instar nymphs cease feeding and enter the pre-emergence behavior characterized by various synchronous or alternating contractions of skeletal muscles. This set of behaviors corresponds to pre-ecdysis in other animals. Emergence or ecdysis behaviors are composed of air swallowing to inflate the gut, as well as peristaltic anteriorly directed movements of the abdomen to push the animal out of the cuticle and other motor programs to extricate legs and appendages on the head. After ecdysis is completed, the new cuticle is expanded within 1 h. The last postexpansional phase is characterized by dorsoventral abdominal contractions during which the gut is deflated and tracheal sacs are filled with air (Hughes, 1980b, 1980c, 1980d).

3.1.6.6. Regulation of Processes Associated With Ecdysis

3.1.6.6.1. Control of molting fluid and air swallowing behaviors The frontal ganglion (FG) controls behaviors associated with the eclosion and feeding of adult *Manduca*. This ganglion innervates dilator and compressor muscles of a cibarial pump in the foregut that develops during metamorphosis. Motoneurons in the FG regulate contractions of the cibarial pump required for swallowing molting fluid many hours before eclosion and air swallowing necessary for wing and abdomen expansion after adult emergence. The pump is later used for feeding of emerged moths (Miles and Booker, 1998). Two types of FG motoneurons have been identified during adult feeding in the FG. These motoneurons are designated anterior and posterior dilator motoneurons (AD1 and PD1, respectively). Since activity of the cibarial pump is regulated by FG neurons during feeding as well as during molting fluid and air swallowing, AD1 and PD1 motoneurons may participate in all these behaviors. Perhaps the FG is also involved in regulation of molting fluid and air swallowing associated with larval and pupal ecdyses.

Application of EH into isolated heads of pharate adults induced within 7–105 min irregular and later rhythmic activity of the cibarial pump muscles corresponding to the air swallowing behavior. This indicates that EH may control this behavior, although natural air swallowing is initiated several hours before EH is thought to be released into the hemolymph, as evidenced by elevation of cGMP in Inka cells. By contrast, ETH injection into whole animals induced premature eclosion, but air swallowing was not initiated, suggesting that ETH may not be involved in this process (Miles and Booker, 1998). However, during normal ecdysis or eclosion ETH causes the EH release, which should induce the behavior. This may indicate that during ETH-induced eclosion, EH was not released, or EH concentrations in the hemolymph were not sufficient to induce air swallowing behavior. Also, mechanisms of EH penetration into the FG and activation of this behavior by EH are not clear and further studies are needed to determine hormonal regulation of neuronal activity in the FG.

Air swallowing behavior leading to new cuticle expansion is associated with larval and adult ecdyses of the locust *Schistocerca* (Bernays, 1971), the cricket *Teleogryllus* (Carlson and Bentley, 1977), the butterfly *Pieris brassicae* (Cottrell, 1964), and the blowfly, *Calliphora erythrocephala* (Cottrell, 1962a). Air swallowing prior to or during ecdysis behaviors is required for expanding the new exoskeleton, which is important for splitting and later shedding of the old cuticle. Freshly emerged adults need air swallowing for inflation of wings and abdomen. Generally, postecdysis air swallowing is necessary for expansion of new soft cuticle to achieve the final shape of the new developmental stage. Neurons and regulatory components controlling swallowing behavior in these insects are not known.

3.1.6.6.2. Regulation of cuticle expansion, sclerotization, and melanization Important postecdysis events include expansion, sclerotization (hardening; see **Chapter 4.4**), and melanization (darkening) of the cuticle. These processes are critical for the normal development of many structures. Some examples include expansion of the proboscis, antennae, legs, and wings in newly ecdysed *Manduca* pupae or adults. The term “tanning” has often been used to describe the combined processes of sclerotization and melanization. Tanning in blowflies could be delayed for hours by forcing newly eclosed flies to dig continuously through artificial substrate following eclosion (Fraenkel, 1935). Only when animals were allowed to break free of substrate would expansion and tanning proceed. Fraenkel also observed that mild anesthesia could abolish the delay, confirming that sensory input is important in the control of tanning. After a 30-year hiatus, a series of papers demonstrated that release of a hormonal factor was critical in the tanning process (Fraenkel and Hsiao, 1962, 1963; Cottrell, 1962a, 1962b, 1962c; Fraenkel, 1965). This factor was named “bursicon,” a term derived from the Greek words “bursa” pertaining to a hide or purse and “bursikos,” meaning a tanning process. Bursicon-like biological activity has been detected in the brain, corpora cardiaca, and ventral ganglia, and release sites are known to be both in the CC and in the transverse nerves of ventral ganglia, i.e., the

perivisceral (perisympathetic) organs (Grillot *et al.*, 1976; Taghert and Truman, 1982a; Honegger *et al.*, 2002).

Various bioassays have been devised to detect bursicon-like bioactivity. The most famous involves use of sarcophagid flies, but the assay works equally well with cyclorraphan flies (Fraenkel, 1965). Flies in the process of emergence are ligated between head and thorax. Because descending input from the brain is essential for bursicon release, no tanning occurs. Injection of tissue extracts containing bursicon into thorax or abdomen result in full tanning within 2 h. Other assays have utilized vermiform locust larvae (Bernays, 1972a), pupal *Tenebrio* (Grillot *et al.*, 1976), and wings from *Manduca* pharate adults (Truman, 1973).

The chemical nature of bursicon was deduced to be peptidic, and numerous independent investigations in different insects demonstrated it to be a large peptide (20–60 kDa) (Fraenkel, 1966; Mills and Lake, 1966; Reynolds, 1977; Taghert and Truman, 1982a). More recent studies have pinpointed its molecular weight closer to 30 kDa in *Periplaneta*, *Locusta*, *Gryllus*, *Tenebrio*, and *Calliphora* (Kostron *et al.*, 1995). The first partial sequences of bursicon have been obtained from *Periplaneta*, and antibodies have been generally useful in visualization of bursicon containing neurons (Honegger *et al.*, 2002).

Bursicon containing neurons were first identified in segmental ganglia of moths using bioassays (Taghert and Truman, 1982a). Owing to the unknown molecular nature of bursicon at the time, this work was done without immunohistochemistry, but rather by dissecting single cell bodies of neurosecretory cells displaying the Tyndall effect and assaying for bursicon bioactivity using the wing assay of Truman. This elegant work demonstrated bursicon content in neurosecretory cells 24, 25, 26, and 27 in unfused abdominal ganglia of *Manduca*. Most of these cells exhibit elevated cGMP levels during the ecdysis behavioral sequence and Cell 27 also contains CCAP (Davis *et al.*, 1993; Ewer and Truman, 1996). Furthermore, these cells project to the perisympathetic organs in the transverse nerve, a known neurohemal release site for bursicon.

Cell 27 is a paired, serially homologous neurosecretory cell in thoracic and abdominal ganglia of *Manduca*, whose homologs have been described in many other insects (**Figures 12 and 13**; Ewer and Truman, 1996; Honegger *et al.*, 2002). A network of Cell 27 homologs was described originally as “lateral A” cells, characterized by their large size, pronounced white appearance due to the Tyndall effect, and strong staining with paraldehyde-fuchsin. They are also characterized by association with large vacuole-like structures adjacent to the cell body (Gaude, 1975). More detailed descriptions of these “lateral white” (LW) cells in crickets and cockroaches showed an association with proctolin-like biological activity, but this has never been confirmed (O’Shea and Adams, 1981). Rather, work from various laboratories has provided definitive evidence for colocalization of bursicon and CCAP in these neurons (Taghert and Truman, 1982a; Adams and Phelps, 1983; Davis *et al.*, 1993). The recent availability of antisera specific for bursicon has confirmed that Cell 27 contains bursicon, and also shows intense bursicon staining in the vacuoles associated with these cell bodies (Honegger *et al.*, 2002). The presence of bursicon staining in these “vacuoles,” together with early ultrastructural work showing that the lumen of the vacuole is continuous with cisternae of the ER, indicate that the vacuole is a large storage depot for secretory product, specialized for large-scale release of hormonal substances into the hemolymph (Adams and O’Shea, 1981). In the cockroach, these cells project axons

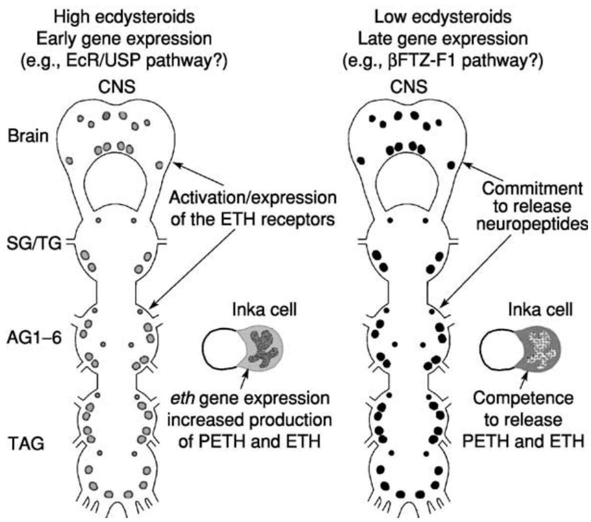

Figure 28 Model for ecdysteroid control of ecdysis in *Manduca*. High ecdysteroid levels induce CNS sensitivity to PETH and ETH. Appearance of this sensitivity indicates expression or activation of the ETH receptors (ETHR) in specific peptidergic and aminergic neurons. High ecdysteroid levels also control expression of the *eth* gene resulting in increased production of PETH, ETH, and their precursors in Inka cells. These processes are mediated by ecdysone receptor (EcR) and other ecdysteroid inducible transcription factors. At this time Inka cells are not competent to release PETH and ETH. Commitment to release CNS neuropeptides (e.g., eclosion hormone) and secretory competence of Inka cells is induced by late gene expression after ecdysteroid levels drop to very low levels at about 6–8 h prior to expected ecdysis. These processes may be mediated by βFTZ-F1 and/or other late transcription factors.

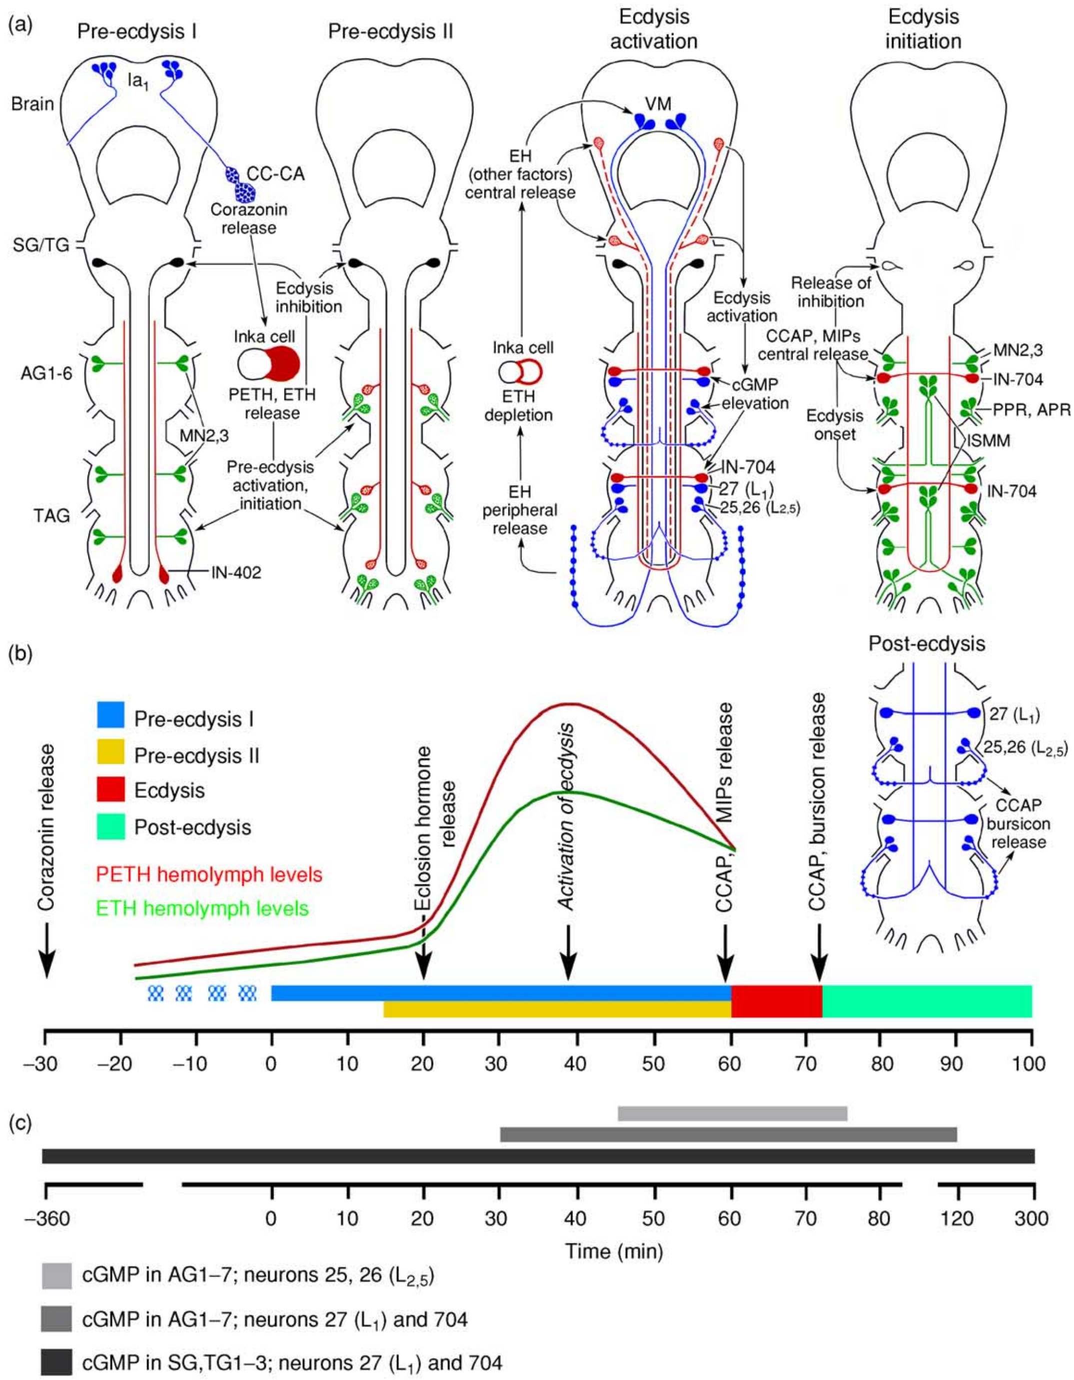

Figure 29 Model for regulation of the *Manduca* ecdysis sequence by peptide hormones. (a, b) Upon receiving sensory input indicating readiness to ecdyse, the CNS releases corazonin into the hemolymph. Corazonin induces the release of PETH and ETH from endocrine Inka cells. PETH and ETH act directly on all AG to initiate pre-ecdysis I and, after a 20 min delay, pre-ecdysis II. Interneurons IN-402 in the TAG control synchronous bursts of paired motoneurons MN-2,3 during pre-ecdysis I. Neurons controlling pre-ecdysis II are hypothetical (stippled cells). About 20 min into pre-ecdysis, EH release elicits massive release of ETH and depletion of Inka cells. Rising levels of ETH act on different targets in the brain (e.g., VM cells) and SG to activate ecdysis and post-ecdysis networks through cGMP elevation in interneurons IN-704 and cells 25–27 ($L_{1,2,5}$) already during pre-ecdysis (a–c). However, inhibitory neurons from the SG and TG1–3 delay ecdysis onset. At the appropriate time, an independent clock in each AG releases descending inhibition, leading to central release of CCAP and MIPs from IN-704 and initiation of ecdysis behavior. Motoneurons MN2,3, PPR, APR, and ISMM control ecdysis contractions. At the end of ecdysis, CCAP and bursicon are released from cells 25–27 ($L_{1,2,5}$) to control cuticle expansion, hardening, and tanning (see text for details). (a) Neurosecretory cells are blue, excitatory interneurons are red, hypothetical inhibitory interneurons are black, and motoneurons are green. (c) Note that cGMP elevation in the SG and TG is obvious several hours prior to ecdysis, while ecdysis activation is associated with cGMP elevation in AG1–7.

not only to the perisympathetic organs, but also in the heart, most likely for general liberation of bursicon into the hemolymph. The corelease of CCAP likely enhances distribution of bursicon to distant locations through its cardioacceleratory activity.

As the Fraenkel bioassay demonstrates, decapitation or ligation behind the head immediately after eclosion inhibits the tanning process. Thus, while most bursicon containing neurons reside in ventral ganglia, they depend on descending input from the cephalic ganglia for activation. Interestingly, *Drosophila* mutants in which CCAP containing neurons have been killed fail to expand or to sclerotize their wings. This indicates that bursicon release depends on activation of CCAP/bursicon-containing neurons, perhaps the Cell 27 homologs.

In order for structures in postecdysial insects to expand, plasticization of the cuticle is necessary. This occurs hours prior to ecdysis in moths. Curiously, even though bursicon is well known to control cuticle hardening, it also seems to be implicated as a plasticizing factor (Fraenkel, 1966; Mills and Lake, 1966; Reynolds, 1977; Taghert and Truman, 1982b). Unfortunately, all of these experiments have been done using tissue extracts and hence mixtures of hormones. It is unclear at the present time how a single hormone can regulate these opposite effects. Definitive assignment of bursicon functions will depend on experiments conducted with chemically pure material or on genetic experiments in which selective knockout of bursicon can be achieved.

In addition to pre-ecdysial plasticization, pre-ecdysial sclerotization of many structures also occurs well before ecdysis (Cottrell, 1962a). These include tanning of tarsal claws, parts of head capsules, and mandibles in moths, and vertical plates, mouth hooks, and sensory structures in flies. It is not clear if bursicon is involved in these pre-ecdysial tanning events; the mechanism(s) of selective tanning of these structures is unknown.

3.1.7. Model

Based on published data from various laboratories and preliminary experiments using *Manduca*, a model has been proposed for hormonal regulation of the ecdysis sequence (**Figures 28–30**). General principles of this model may apply to other insects, but there are several important differences in the regulation of ecdysis in *Bombyx* and especially in *Drosophila*, as discussed above (see Section 3.1.6.6). Successful ecdysis depends on a signaling cascade consisting of ecdysteroid and peptide hormones. Several days prior to ecdysis, high ecdysteroid levels act on Inka cells to induce expression of the ecdysteroid receptor (EcR) and the ETH gene, which results in increased production of PETH, ETH, and their precursors in Inka cells. However, high ecdysteroid levels suppress secretory competence of Inka cells to release PETH and ETH. Peak ecdysteroid levels also induce sensitivity of the CNS to Inka cell peptides. This sensitivity indicates that ecdysteroids control expression of ETH receptors (ETHR) oractivation of signal transduction in specific neurons (**Figure 28**). Specific gene expression induced by

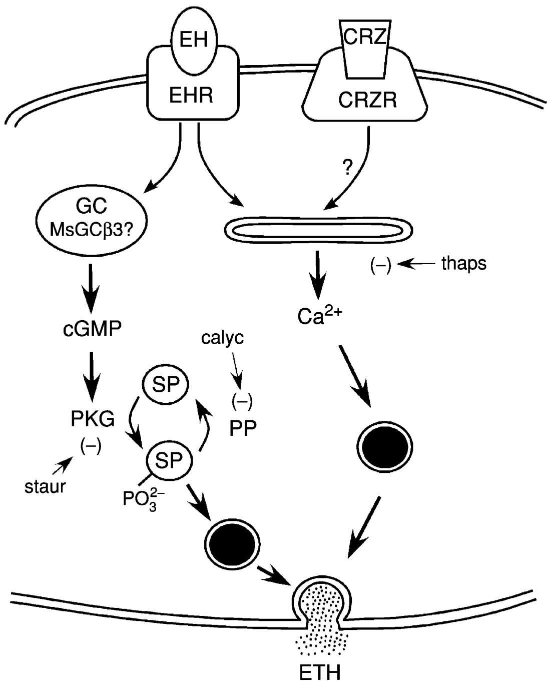

Figure 30 Model for corazonin and EH induced release of ETH from Inka cells in *Manduca*. Release of corazonin from the brain-CC–CA causes activation of its receptor (CRZR) in Inka cells resulting in secretion of PETH and ETH and initiation of pre-ecdysis (Kim *et al.*, 2004). Signal transduction mechanisms coupling receptor activity with peptide release are unknown, but this secretion may occur through liberation of calcium from intracellular stores. About 30 min into pre-ecdysis, EH action on Inka cells causes elevation of both cGMP and calcium, leading to massive depletion of ETH, whose direct action on the CNS activates the ecdysis network. EH-induced secretion occurs through parallel cGMP and calcium pathways. A soluble, NO-insensitive guanylate cyclase (MsGC-β3) mediates the action of EH to form cGMP, which in turn activates protein kinase G (PKG) (Morton and Simpson, 2002). A hypothetical substrate protein (SP) facilitates ETH release, which is augmented by the phosphatase inhibitor calyculin (calyc). The broad-spectrum kinase inhibitor staurosporine (staur) blocks ETH release, but not cGMP elevation, suggesting that its action is downstream. Release of calcium from thapsigargan-sensitive intracellular stores also contributes to release as a parallel signal transduction pathway. (Modified from Kingan, T.G., Cardullo, R.A., Adams, M.E., **2001**. Signal transduction in eclosion hormone-induced secretion of ecdysis-triggering hormone. *J. Biol. Chem. 276* (27), 25136–25142.)

peak ecdysteroid levels enables the CNS to respond to PETH and ETH and to execute the ecdysis sequence. However, these peptide hormones are released only following ecdysteroid decline several hours or days later. Declining ecdysteroid levels are required for late gene expression, which elicit secretory competence in Inka cells. Ecdysteroid decline is also required for commitment of some neurons to release central neuropeptides (e.g., EH). Expression of β-FTZ-F1 coincides with the appearance of secretory competence in Inka cells, suggesting that this transcription factor may participate in regulation of this process.

The initial secretion of PETH and ETH from Inka cells appears to be regulated by the neuropeptide corazonin (**Figures 29 and 30**). It is not known what factors control corazonin release, but it is speculated that sensory input to the brain may determine when the animal is ready to initiate the ecdysis sequence. Release of corazonin from the CC–CA causes secretion of Inka cell peptides (PETH and ETH) into the hemolymph. Other neuropeptides released from the ventral nerve cord and gut may be involved in regulation of PETH and ETH secretion. Low levels of PETH and ETH then act on abdominal ganglia to activate motor programs for pre-ecdysis I and II. In *Manduca*, PETH is a specific signal for activation of pre-ecdysis I, but ETH can activate both pre-ecdysis I and pre-ecdysis II neuronal circuitry in the absence of PETH. During pre-ecdysis I, interneurons IN-402 in the posterior TAG region have been identified to control synchronous bursts of paired motoneurons MN-2,3 in abdominal ganglia and corresponding dorsoventral contractions (Novicki and Weeks, 1995). Approximately 15–20 min later, ETH acts on additional neurons in each abdominal ganglion to induce posterioventral and proleg contractions (pre-ecdysis II). The principal modulatory neurons and their neurotransmitters that activate pre-ecdysis I and II networks within the CNS remain to be identified (**Figure 29**).

At the same time, ETH acts on the brain VM neurons and additional neurons in the tritocerebrum and SG to induce central and peripheral release of EH and other factor(s). Peripheral release of EH causes cGMP elevation and depletion of peptide hormones in Inka cells (**Figure 30**), while central release of EH and other factor(s) activates the abdominal ecdysis network. This network is composed of paired neurons 25–27 ($L_{1,2,5}$) and IN-704 producing CCAP, MIPs, and/or bursicon. Although cGMP elevation in this network is apparent already 30 min into natural pre-ecdysis, animals switch to ecdysis behavior much later. The delay from activation of the CCAP/MIP network to the onset of ecdysis behavior is controlled by putative descending inhibitory neurons from the SG and TG1–3 (see Section 3.1.6.1). The switch from pre-ecdysis to ecdysis is probably controlled by the central release of CCAP and MIPs from IN-704. MIPs suppress activities of excitatory and inhibitory neurons controlling proper execution of pre-ecdysis motor programs, while CCAP initiates the ecdysis motor program. CCAP may modulate activities of several motoneurons (MN2,3, ISM, PPR, and APR) controlling ecdysis movements (**Figure 29**; Weeks and Truman, 1984a, 1984b). After the old cuticle is shed, sensory input likely reactivates inhibitory neurons to stop ecdysis movements. Bursicon and CCAP are probably released after ecdysis from cells 25–27 ($L_{1,2,5}$) to regulate tanning and hardening of the cuticle.

Mechanisms mediating activation and initiation of different CNS motor programs by PETH and ETH are not known. The authors propose that Inka cell peptides bind to their receptors (ETHR-A and ETHR-B) expressed in a network of various peptidergic and/or aminergic neurons. The ETH receptor binding leads to a cascade of biochemical reactions controlling subsequent and precisely timed release of specific neuropeptides and neuroamines. These regulatory molecules then modulate different neuronal networks involved in pre-ecdysis and ecdysis behaviors. Thus, receptor mediated actions of PETH and ETH on different CNS ganglia are necessary for activation of specific neuronal networks, which then release central stimulatory or inhibitory factors controlling timing and performance of pre-ecdysis and ecdysis behaviors. Several of these ecdysis-specific central regulators have been identified (e.g., EH, CCAP, and MIPs), but many additional factors are expected to be essential for execution of pre-ecdysis I and pre-ecdysis II, as well as inhibition and activation of ecdysis. Identification of neurons expressing receptors for ETH, EH, CCAP, MIPs, and other "ecdysis" neuropeptides and neuroamines will provide tools for shedding more light on complex neuroendocrine interactions dedicated to shedding of the old cuticle.

Acknowledgments

We thank Y.-J. Kim, I. Spalovská-Valachova, I. Zitnanová, and L. Roller for their comments on the manuscript and technical assistance. We also thank Drs M. Blackburn, H. Dircksen, E. Marder, and Y. Tanaka for generous gifts of antisera to MIP I, CCAP, FMRFamide, and corazonin, respectively. This work was supported by grants from

the National Institute of Health (AI 40555 and GM067310) and Vedecká grantová agentúra (95/5305/800 and 2/7168/20).

3.2 Prothoracicotropic Hormone

R Rybczynski, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

3.2.1. General Introduction and Historical Background

The evolution of multicellular organisms possessing multiple cell types has required the coevolution of a variety of intercellular signals. These signals coordinate and control the multiplication and differentiation of a multitude of cell types from a single, initial zygotic cell. These signals also coordinate and control the interaction of these various cell types throughout the life of an organism. In vertebrates familiar to most people, i.e., reptiles, birds, and mammals, a newborn or hatched individual is generally not strikingly different from an adult and postembryonic development is relatively gradual; altricial birds and marsupials are exceptions in that individuals of these groups undergo embryonic-like development for a period of time after hatching or birth (see Truman and Riddiford, 2002). However, even in these latter vertebrate groups, developmental changes are gradual and do not involve relatively sudden and major changes in morphology and physiology. In contrast, many invertebrates, including insects, undergo striking and periodic postembryonic changes in the rate of development and in morphology and physiology. The physical growth of insects is restricted by the extracellular cuticle, which is limited in its ability to accommodate expansion. Insects solve this problem by periodic molts in which the old cuticle is partly resorbed and partly shed and a new cuticle is laid down, allowing for a further period of growth. In addition, many insects undergo molts in which significant changes in structure occur, i.e., metamorphic molts (for more thorough discussions on the evolution of metamorphosis, see Sehnal *et al*., 1996; Truman and Riddiford, 2002). Controlling and coordinating these episodes of rapid developmental change is a suite of intercellular messengers (hormones). The

polyhydroxylated steroid hormone, 20-hydroxyecdysone (20E) is a major factor regulating molting and metamorphosis. 20E is produced from ecdysone (E), which itself has some hormonal activity (see **Chapters 3.3** and **3.5**). This chapter focuses on prothoracicotropic hormone (PTTH), a brain neuropeptide hormone, and its action in regulating the physiology of the prothoracic gland. For the actual pathway of ecdysteroid synthesis, starting with cholesterol or other sterols, the reader is directed to (see **Chapter 3.3**).

It must be stated at the outset that the vast majority of data and discussion presented in this chapter come from studies of the Lepidoptera, especially the moth species *Manduca sexta* (tobacco hornworm) and *Bombyx mori* (domestic silkmoth), simply because we have much more knowledge of PTTH or PTTH-like activity from this taxon than from any other group. The first section of this chapter reviews the field of PTTH research from the 1920s to the early 1980s; for further and more detailed pictures of this time period, see reviews by Ishizaki and Suzuki (1980), Gilbert *et al.* (1981); Granger and Bollenbacher (1981); Ishizaki and Suzuki (1984) and Bollenbacher and Granger (1985), among others.

In the second and third decades of the twentieth century, the Polish biologist Stefan Kopeć first provided evidence that the brain could control metamorphosis (e.g., Kopeć, 1922). Kopeć studied the larval–pupal molt of the gypsy moth, *Lymantria dispar*, employing simple techniques like the ligation of larvae into anterior and posterior sections, and brain extirpation. His data demonstrated that the larval–pupal molt of the gypsy moth was dependent upon the brain during a critical period in the last instar larval stage. After this stage, head ligation failed to prevent pupation. Kopeć (1922) found also that this control was not dependent on intact nervous connections with regions posterior to the brain. The studies of Kopeć represent the beginning of the field of neuroendocrinology but their importance was not recognized at the time. However, later workers, notably Wigglesworth, took similar approaches with other species of insects and demonstrated again that the brain was important for larval molting at certain critical periods and that the active principle appeared to be produced in a part of the brain containing large neurosecretory cells (e.g., Wigglesworth, 1934, 1940).

In the same time period, other studies, again using simple techniques like transplantation and transection, found that the brain-derived factor was not sufficient to stimulate molting and metamorphosis. Rather, a second component produced in the thorax was necessary (e.g., Burtt, 1938; Fukuda, 1941; Williams 1947). This material originated in the prothoracic gland or ring gland and was later shown to be an ecdysteroid precursor to 20E, i.e., 3dE in Lepidoptera (Kiriishi *et al.*, 1990), or E and makisterone A in *Drosophila* (Pak and Gilbert, 1987) (see **Chapter 3.3**).

The chemical nature of PTTH was addressed in studies beginning in 1958, when Kobayashi and Kimura (1958) found that high dose of an ether extract of *B. mori* pupal brains was able to induce adult development in a *Bombyx* dauer pupa assay. This result suggested that PTTH was a lipoidal moiety, such as a sterol. In contrast, Ichikawa and Ishizaki (1961) found that a simple aqueous extract of *Bombyx* brains could elicit development in a *Samia* pupal assay, an observation not supporting a lipoidal nature for PTTH, and in a later study, provided direct evidence that *Bombyx* PTTH was a protein (Ichikawa and Ishizaki, 1963). Schneiderman and Gilbert (1964), using the *Samia* assay, explicitly tested the possibility that PTTH was cholesterol or another sterol and concluded that a sterol PTTH was highly unlikely. During the 1960s and 1970s, data accumulated from a number of studies indicated that *Bombyx* PTTH was proteinaceous in nature, but attempts to ascertain the molecular weight yielded at least two peaks of activity, one $\leq$5 kDa and a second $\geq$20 kDa (e.g., Kobayashi and Yamazaki, 1966).

In the 1970s and 1980s, a second lepidopteran, the tobacco hornworm *M. sexta*, gained favor as a model organism for the elucidation of the nature of PTTH. Initial experiments with *Manduca* utilized a pupal assay (Gibbs and Riddiford, 1977) but a system measuring ecdysteroid synthesis by prothoracic glands *in vitro* soon gained prominence (Bollenbacher *et al.*, 1979). Using the pupal assay, Kingan (1981) estimated the molecular weight of *Manduca* PTTH to be $\approx$25 kDa. A similar estimate (MW $\approx$29 kDa) resulted from assays employing the *in vitro* technique but this approach also provided evidence for a second, smaller PTTH (MW = 6–7 kDa) (Bollenbacher *et al.*, 1984).

The site of PTTH synthesis within the brain was first investigated by Wigglesworth (1940) who, by implanting various brain subregions into host animals, identified a dorsal region of the *Rhodnius* brain containing large neurosecretory cells as the source of PTTH activity. Further studies, in species such as *Hyalophora cecropia*, *Samia cynthia* and *M. sexta*, also provided evidence that PTTH was produced within regions of the dorsolateral or medial-lateral brain that contained large neurosecretory cells. This methodology was refined and ultimately culminated in the identification of the

source of PTTH as two pairs of neurosecretory cells (one pair per side) in the brain of *Manduca* (Agui *et al.*, 1979).

The corpus cardiacum (CC) of the retrocerebral complex was originally suggested to be the site of PTTH release, based on structural characteristics of the organ and the observation that axons of some cerebral neurosecretory cells terminate in the CC. However, physiological studies involving organ transplants and extracts implicated the corpus allatum (CA), the other component of the retrocerebral complex, as the site of PTTH release. *In vitro* studies utilizing isolated CCs and CAs from *Manduca* revealed that the CAs contained considerably more PTTH than CCs (Agui *et al.*, 1979, 1980). This result was also obtained when high levels of potassium were used to stimulate PTTH release from isolated CCs and CAs; potassium caused a several-fold increase in PTTH release from both organs (Carrow *et al.*, 1981) but the increase from CCs barely matched the spontaneous release from CAs. PTTH activity in the CC could be explained by the fact that axons that terminate in the CA traverse the CA and isolation of the CC would carry along any PTTH caught in transit through this organ. Additional evidence that the CAs are the neurohemal organ for the PTTH-producing neurosecretory cells was the observation that CA PTTH content correlated positively with brain PTTH content (Agui *et al.*, 1980).

The episodic nature of insect growth and morphological development reflects, *in sensu latu*, the periodic peaks of circulating molting hormone, i.e., 20E. The existence of these ecdysteroid peaks implies that peaks in PTTH synthesis and release also exist. A variety of studies tried to determine when PTTH peaks occur and what factors influence the release of PTTH into the hemolymph. Wigglesworth (1933) performed pioneering studies on the control of *Rhodnius* PTTH release. He found that distension of the intestinal tract was the most important determinant of blood meal-dependent molting. Multiple small meals were not effective but artificially increasing distension by blocking the anus with paraffin notably decreased the size of a blood meal required. A meal of saline can also trigger (but not sustain) a molt, indicating that for *Rhodnius* at least, nutritional signals are not critical (Beckel and Friend, 1964). Meal-related distension appears to be sensed by abdominal stretch or pressure receptors in insects such as *Rhodnius* (Wigglesworth, 1934) (see **Chapter 3.9**). This type of regulation is not surprising in blood-sucking insects that rapidly change the fill state of their gut but, somewhat surprisingly, it appears also to occur in some insects that are continuous rather than episodic feeders, like the milkweed bug, *Oncopeltus fasciatus* (Nijhout, 1979). In this species, subcritical weight nymphs inflated with air or saline will commence molting.

In many other insects, the physical and physiological conditions that permit and control PTTH release are subtle and partially known. In *Manduca*, it appears that a critical weight must be achieved before a molt is triggered (Nijhout, 1981); however, this weight is not a fixed quantity. Rather, the critical weight is a function of the weight and/or size at the time of the last molt. Animals that were very small or very large at the fourth to fifth larval instar molt will exhibit critical weights smaller or larger than the typical individual. Further complications revolve around the element of time. Animals that remain below critical size for a long period may eventually molt to the next stage (*Manduca*: Nijhout, 1981), or undergo stationary larval molts without growth (*Galleria mellonella:* Allegret, 1964). PTTH release may also be a "gated" phenomenon. That is, PTTH release occurs only during a specific time of the day and only in animals that meet critical criteria, like size, weight or allometric relationships between structures or physiological variables. Individuals that reach critical size within a diel cycle but after that day's gate period will not release PTTH until the next gate on the following day (see **Chapter 3.3**).

The concept of a critical size or similar threshold parameter that must be met to initiate PTTH release implies that there will be a single PTTH release per larval instar. This appears to be true through the penultimate larval instar but careful assessment of PTTH activity in *Manduca* hemolymph revealed two periods of significant levels of circulating PTTH during the last larval instar (Bollenbacher and Gilbert, 1981). In this species, three small PTTH peaks were seen about 4 days after the molt to the fifth instar while a single larger peak occurred about 2 days later. The first period of PTTH release is gated but the second appears to be neither gated nor affected by photoperiod (Bollenbacher, unpublished data cited in Bollenbacher and Granger, 1985). These two periods of higher circulating PTTH correspond to the two head critical periods (HCPs) that are found in the last larval instar of *Manduca*. HCPs represent periods of development before which the brain is necessary for progression to the next molt, as determined by ligation studies. In the fifth (last) larval instar of *Manduca*, the two periods of higher hemolymph titers of PTTH activity immediately precede and partially overlap two peaks in circulating ecdysteroids (Bollenbacher and Gilbert, 1981). The first small ecdysteroid peak

determines that the next molt will be a metamorphic one (the commitment peak: Riddiford, 1976) while the second large peak actually elicits the molt.

The existence of daily temporal gates for PTTH release suggested that a circadian clock plays a role in molting and metamorphosis (see **Chapters 3.11** and **4.11**). In fact, such a clock does appear to function in *Manduca* because shifting the photoperiod shifted the time of the gate (e.g., Truman, 1972). Furthermore, the entrainment of this circadian cycling was not dependent on retinal stimulation because larvae with cauterized ocelli still reacted to photoperiodic cues (Truman, 1972). A more overarching effect of photoperiod can be seen in the production of diapause (see **Chapter 3.12**). For instance, in *Antheraea* and *Manduca*, which exhibit pupal–diapause, short days experienced during the last larval instar result in the inhibition of PTTH release during early pupal–adult development (e.g., Williams, 1967; Bowen *et al*., 1984a); the brain PTTH content of these diapausing pupae and that of nondiapausing pupae are similar, at least at the beginning of the pupal stage. Temperature often plays an important role in breaking diapause and an elevation of temperature has been interpreted to cause the release of PTTH (Bollenbacher and Granger, 1985), with a resultant rise in circulating ecdysteroids that triggers the resumption of development. The interposition of hormonal signals between light-cycle sensing and the inhibition of PTTH release and/or synthesis can involve the juvenile hormones (JHs). In species exhibiting larval diapause, like *Diatraea grandiosella*, the persistence of relatively high JH levels controls diapause (e.g., Yin and Chippendale, 1973). Ligation experiments indicated that the head was involved in JH-related larval diapause, resulting in the suggestion that JH inhibited the release of an ecdysiotropin, i.e., PTTH (Chippendale and Yin, 1976).

In summary, by the time of the publication of *Comprehensive Insect Physiology, Biochemistry and Pharmacology* in 1985, PTTH had progressed from being an undefined brain factor controlling molting (Kopeć, 1922) to being identified as one of two brain neuropeptides that specifically regulated ecdysteroid synthesis in the prothoracic gland (e.g., Bollenbacher *et al*., 1984), and that was synthesized in a very limited set of brain neurosecretory cells (Agui *et al*., 1979). In the remainder of this chapter, the characterization and purification of PTTH will be detailed, as will the intracellular signaling pathways by which PTTH activates the prothoracic gland. On the whole, this phase of PTTH research has involved more complicated biochemical and cell biological experiments than earlier work. However, even though the methodology described has become more complicated and specialized, it is hoped that the discussions and speculations presented in this phase will remain as broad and as "biological" as those generated during that earlier, "simpler" period of PTTH research.

3.2.2. Prothoracicotropic Hormone (PTTH): Characterization, Purification, and Cloning

3.2.2.1. Purification and Cloning of the PTTHs of *Bombyx* and other Lepidoptera

Two species of Lepidoptera, *B. mori* and *M. sexta*, have emerged as the premier model species for studying the endocrinology of insect molting and metamorphosis. As described above, evidence suggested that, for these species, PTTH activity resided in proteins exhibiting two distinct molecular weights, one of 4–7 kDa and the second of 20–30 kDa. Early work with *Bombyx* brain extracts utilized a cross-species assay to determine PTTH activity. This assay, using debrained *Samia* pupae, suggested that the most effective *Bombyx* PTTH (4K-PTTH) was the smaller protein. However, as efforts to purify and further characterize *Bombyx* PTTH progressed, a *Bombyx* pupal assay was developed (Ishizaki *et al*., 1983a). This assay revealed that when *Bombyx* PTTH preparations were tested with debrained *Bombyx* pupae, *Bombyx* PTTH appeared to be the larger molecule while the small PTTH, identified with the *Samia* assay, was not effective at physiologically meaningful doses (Ishizaki *et al*., 1983a,1983b). This result was confirmed when the small and large PTTHs were tested for their ecdysteroidogenic effect *in vitro* on *Bombyx* prothoracic glands (Kiriishi *et al*., 1992).

The effort to isolate and sequence *Bombyx* PTTH shifted rapidly to the "large" PTTH form following the 1983 results; the smaller molecule, subsequently named bombyxin, is discussed briefly below (see Section 3.2.2.5). Within a few years, the sequence of the amino terminus (13 amino acids) of *Bombyx* PTTH (called 22K-PTTH in the publications of the day) was obtained after a purification effort that involved processing 500 000 adult male heads (Kataoka *et al*., 1987). The final steps of this purification involved HPLC separations of proteins and this technique suggested that PTTH might exhibit heterogeneity in sequence and/or structure. However, the nature of that heterogeneity was unknown, since only one of four potential PTTH peaks was sequenced. In addition to this limited amount of amino acid sequence, this study is significant since

it demonstrated that *Bombyx* PTTH was indeed a protein, and one that had no sequence homology to other proteins known at that time, including bombyxin. Also, significant was the finding that PTTH was highly active when injected into brainless *Bombyx* pupae. A dose of only 0.11 ng was as effective as 100–400 ng of bombyxin, thus demonstrating again that bombyxin was not the *Bombyx* PTTH (Kataoka *et al.*, 1987). A second round of *Bombyx* PTTH purification was initiated, using 1.8 million heads (derived from 1.5 tons of moths!), and this heroic effort resulted in the determination of nearly the entire PTTH amino acid sequence (104 amino acids), except for a small fragment (5 amino acids) at the C-terminus (Kataoka *et al.*, 1991). At the same time, the N-terminus sequence was used to produce a polyclonal mouse antibody against *Bombyx* PTTH, which was then successfully utilized in a cDNA expression library screening (Kawakami *et al.*, 1990). The empirically determined and deduced amino acid sequences of *Bombyx* PTTH agreed completely in the region of overlap. Furthermore, the amino acid sequence deduced from the cDNA sequence indicated that, like many neuropeptides, *Bombyx* PTTH appeared to be synthesized as a larger, precursor molecule (**Figure 1**). Two slightly smaller sequences of PTTH were also obtained during the larger PTTH purification (Kataoka *et al.*, 1991), which were missing six or seven amino acids from the N-terminal sequence obtained from the largest peptide. It is not known if this N-terminus heterogeneity was an artifact of sample storage or purification methods, or reflected a natural variation with possible biological effects on activity. A more detailed analysis of the amino acid sequence and structure of *Bombyx* PTTH and other PTTHs is provided in Section 3.2.2.3

The large number of brains required to purify PTTH has precluded attempts to purify this protein from species other than *Bombyx*, with the exception of *M. sexta*. For *Manduca*, Bollenbacher and colleagues raised a monoclonal antibody against a putative purified big PTTH (O'Brien *et al.*, 1988) and used this antibody to construct an affinity column. This immunoaffinity column was then used to attempt a purification of *Manduca* PTTH from an extract made from about 10 000 brains (Muehleisen *et al.*, 1993). Partial amino acid sequences obtained from a protein purified via this affinity column showed no sequence homology with *Bombyx* PTTH; instead, the isolated protein appeared to be a member of the cellular retinoic acid binding protein family (Muehleisen *et al.*, 1993; Mansfield *et al.*, 1998). This surprising result was in direct contrast to the finding of Dai *et al.* (1994) that an anti-*Bombyx* PTTH antibody recognized only the cells previously identified as the *Manduca* prothoracicotropes by Agui *et al.* (1979), and the observation that *Manduca* PTTH could be immune-precipitated by an anti-*Bombyx* PTTH antibody (Rybczynski *et al.*, 1996). In the latter case, the immune-precipitated *Manduca* PTTH could be recovered in a still-active state (Rybczynski *et al.*, 1996). Subsequently, the isolation of a *Manduca* PTTH cDNA, utilizing a *Bombyx* probe, and expression of the derivative recombinant *Manduca* PTTH confirmed that *Manduca* PTTH was indeed related to the *Bombyx* molecule (Gilbert *et al.*, 2000; Shionoya *et al.*, 2003). In an earlier molecular approach, Gray *et al.* (1994) used the polymerase chain reaction with *Bombyx* PTTH-derived sequences to probe *Manduca* genomic DNA and a neuronal cDNA library. This search yielded an intronless sequence differing in only two amino acids from *Bombyx* PTTH but quite different from the *Manduca* PTTH later demonstrated to exhibit bioactivity (Gilbert *et al.*, 2000); note that the gene for *Bombyx* PTTH contains five introns (Adachi-Yamada *et al.*, 1994). This unexpected result, suggesting that *Manduca* may have a second large PTTH has not been

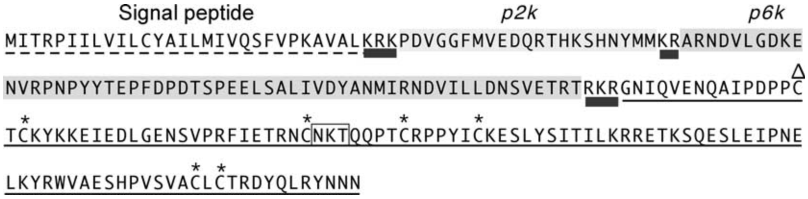

Figure 1 Amino acid sequence and main features of *Bombyx* PTTH. Dashed underlining: the putative signal peptide region; thin solid underlining: the mature, bioactive peptide; thick underlining: predicted peptide cleavage sites; light shading: putative 2-kDa peptide; dark shading: putative 6-kDa peptide; boxed amino acids: glycosylation site; ∗: cysteines involved in intramonomeric bonds; and Δ: cysteine involved in dimer formation. further pursued. Evidence suggesting that the *Manduca* brain might express a small PTTH in addition to the larger peptide is discussed in Section 3.2.2.5 Additional molecular studies, again using probes derived from the *Bombyx* PTTH sequence, have yielded lepidopteran PTTH sequences from three additional species: *Samia cynthia ricini* (Ishizaki and Suzuki, 1994); *Antheraea pernyi* (Sauman and Reppert, 1996a); and *H. cecropia* (Sehnal *et al.*, 2002) (see the following section). Recombinant *Antheraea* PTTH has been expressed and shown to have bioactivity, being capable of inducing adult development in debrained pupae (Sauman and Reppert, 1996a). The bioactivity of the proteins coded for by the *Samia* and *Hyalophora* sequences has not yet been tested.

Preliminary determinations of the molecular weight of PTTH have been made recently for a few additional lepidopteran species, such as the gypsy moth *L. dispar* (Kelly *et al.*, 1992; Fescemyer *et al.*, 1995), primarily using *in vitro* assays of ecdysteroidogenesis and variously treated brain extracts. These studies revealed two molecular weight ranges for PTTH, i.e., small and large. However, the molecular weight obtained for the large *Lymantria* PTTH (11 000–12 000) varied notably from those determined for the purified and cloned forms such as *Bombyx* PTTH (native weight ≈ 25 000–30 000). This difference is probably a function of the sample treatment (acidic organic extraction versus aqueous extraction) and molecular weight analysis methods (HPLC versus SDS-PAGE), since when essentially the same extraction and HPLC methodology were applied to *Manduca* brain extracts, a similarly low molecular weight determination for “big” PTTH was obtained (11.5 kDa; Kelly *et al.*, 1996).

3.2.2.2. Characterization of the PTTH of Non-Lepidoptera

Despite the importance of the hemipteran *Rhodnius* in early studies demonstrating a brain-derived prothoracicotropic factor (e.g., Wigglesworth, 1934, 1940), relatively little work has been done on molecularly characterizing PTTH activity from species other than lepidopterans. In *Rhodnius*, Vafopoulou *et al.* (1996) found that brain extracts contained a protease-sensitive PTTH activity (see **Chapter 2.4**). Later work suggested that this activity was greater than 10 kDa in molecular weight when immunoblots of *Rhodnius* brain proteins or medium from *in vitro* incubations of brains were probed with an antibody against *Bombyx* PTTH (Vafopoulou and Steel, 2002). If nonreducing gel conditions were used, the strongest immunoreactive band was ≈68 kDa, but reducing conditions yielded only a single band at ≈17 kDa. This latter molecular weight is the same as that calculated for *Bombyx* PTTH under reducing electrophoresis conditions (Mizoguchi *et al.*, 1990). It is also very similar to the molecular weights determined for *Manduca* PTTH, again employing the *Bombyx* antibody after reducing SDS-PAGE (≈16 kDa; Rybczynski *et al.*, 1996), and for the *Antheraea* PTTH, using an *Antheraea* PTTH antibody and strong reducing conditions (≈15 kDa; Sauman and Reppert, 1996a). Also, as demonstrated earlier for *Manduca* brain extract (Rybczynski *et al.*, 1996), an anti-*Bombyx* PTTH antibody removed PTTH activity from a *Rhodnius* brain extract (Vafopoulou and Steel, 2002).

The growing use of *Drosophila melanogaster* as a model organism for the study of development, neuronal function, and many other fields has not been accompanied by a concomitant increase in our knowledge of *Drosophila* PTTH. The small size and rapid development of *Drosophila* have made it difficult to perform classic endocrinology on this species, e.g., measuring ecdysteroid titers, accumulating large quantities of brain proteins, or isolating the ring gland for *in vitro* studies of ecdysteroid synthesis. In addition, the composite nature of the ring gland, which contains multiple cell types in addition to the prothoracic gland cells, complicates the interpretation of experiments in a way that is not seen with the moth glands. Nevertheless, an *in vitro* assay for ring gland ecdysteroid synthesis has been developed (Redfern, 1983) and used to search for PTTH activity. The results of these studies have not yielded a clear or consistent picture of *Drosophila* PTTH, nor, in fact, conclusive evidence that *Drosophila* possesses a PTTH that is much like the lepidopteran molecules.

In a series of studies, Henrich and collaborators characterized PTTH activity from the central nervous system of *Drosophila* (Henrich *et al.*, 1987a, 1987b; Henrich, 1995). They found that PTTH activity was present in both the brain and in the ventral ganglion; the latter location is in contradistinction to the Lepidoptera where PTTH activity is found only in the brain and in the corpus allatum, the neurohemal organ for PTTH release. Note that in *Drosophila* and other higher flies, the ring gland, which contains the prothoracic gland, also includes the corpus allatum. Also relevant is the finding that an antibody against *Bombyx* PTTH bounds to specific cells both in the brain and in ventral ganglionic regions of *Drosophila* (Žitňan *et al.*, 1993), thus supporting the conclusion of Henrich (1995) that *Drosophila* PTTH activity was not restricted to the brain. An attempt to estimate the molecular weight

of this putative PTTH yielded equivocal results. Ultrafiltration through a 10-kDa filter resulted in PTTH activity in both the filtrate and retentate (Henrich, 1995). This might indicate the presence of two PTTH-like molecules, i.e., a big and a small PTTH, or simply the presence of a single PTTH of a molecular weight and shape that results in incompletely partitioning under the ultrafiltration protocol employed.

Two other studies yielded very different estimates of *Drosophila* PTTH molecular weight. Pak *et al.* (1992), using column chromatography, found two peaks of PTTH activity, one of ≈4 kDa and the other larger, at ≈16 kDa. In contrast, Kim *et al.* (1997), using a more complex chromatographic purification, concluded that *Drosophila* PTTH was a much larger, heavily glycosylated molecule of ≈66 kDa, with a core protein of ≈45 kDa. This group also subjected two reduced fragments of their purified PTTH to amino acid sequence analysis and found no homology with other protein sequences known at that time. However, a search of the current *Drosophila* molecular databases revealed that the sequence of these two fragments match portions of the deduced amino acid sequence encoded by *Drosophila* gene BG:*DS000180.7* (unpublished analysis). This protein is cysteine-rich, with a MW of ≈45 kDa, and contains sequence motifs that place it in the EGF protein family, thus suggesting that it is a secreted protein. Based on its sequence, the *DS000180.7* gene product has been hypothesized to be involved in cell–cell adhesion (Hynes and Zhao, 2000). As a member of the EGF family of proteins, the *DS000180.7* gene product cannot be ruled out as an intercellular signaling molecule, i.e., as a prothoracicotropic hormone, without a functional test. What is clear currently, is that this protein shows no detectable amino acid similarity to the demonstrated PTTHs of the Lepidoptera (unpublished analysis), when compared with those sequences using a standard comparison program like Basic Local Alignment Search Tool (BLAST) (Altschul *et al.*, 1990).

Further clouding the interpretation of the *Drosophila* PTTH studies was the requirement for relatively large amounts of putative PTTH material that was also, relative to lepidopteran material, comparatively poor in eliciting increased ecdysteroidogenesis. Thus, in the *Drosophila* studies, Henrich and coworkers (Henrich *et al.*, 1987a, 1987b; Henrich, 1995) and Pak *et al.* (1992) needed to use approximately eight brain-ventral ganglion equivalents of extract to stimulate ecdysteroid synthesis to two to three times basal, while Kim *et al.* (1997) employed 500 ng of purified protein to achieve a similar activation. In contrast, lepidopteran PTTHs are effective at much lower doses; for instance, in *Manduca*, 0.25 brain equivalents or 0.25–0.5 ng of pure PTTH consistently results in a four to six times increase in ecdysteroidogenesis (Gilbert *et al.*, 2000) and activations of steroidogenesis of eight to ten times basal are not rare (personal observation). Further differences between putative *Drosophila* PTTH(s) and the lepidopteran PTTHs are discussed below (see Section 3.2.3.4). In addition to the work just discussed, the *Drosophila* genome project has offered a second approach to identify a PTTH candidate for this species. A search of this database with lepidopteran PTTH amino acid sequences revealed two candidate *Drosophila* sequences with intriguing similarities to the moth PTTHs and these are discussed in the next section.

Mosquitoes, such as the African malaria mosquito *Anopheles gambiae* and the yellow fever mosquito *Aedes aegypti,* are important disease vectors and have been the subject of many studies incorporating basic and applied approaches to their biology and control. In adult females of these species, a blood meal stimulates both the release of brain-derived gonadotropins (see **Chapter 3.9**), like ovary ecdysteroidogenic hormone, and of insulin-like molecules that stimulate ovarian ecdysteroid synthesis. Preadult development in mosquitoes appears to depend on ecdysteroid hormones, as in other insects; however, the morphological source of ecdysteroid production is not clear. Jenkins *et al.* (1992) provided evidence that the prothoracic gland of *A. aegypti*, which is part of a composite, ring gland-like organ, is inactive and that unknown cell types in the thorax and abdomen produce ecdysteroids. At the time of writing (2003), a genome-sequencing project is also under way for *A. aegypti* but the limited database currently available does not contain any putative PTTH homologs. However, in this context it is intriguing that the genome of *A. gambiae* might code for a PTTH-like protein. Searches of the *A. gambiae* genome database with lepidopteran and putative *Drosophila* PTTH amino acid sequences reveal two candidate gene products, which are discussed in the next section.

Antibodies against PTTH afford an additional tool to search for PTTH-like proteins and have been used in a number of studies, in addition to the immunoprecipitations of *Manduca, Drosophila*, and *Rhodnius* studies discussed above (Žitňan *et al.*, 1993; Dai *et al.*, 1994; Rybczynski *et al.*, 1996; Vafopoulou and Steel, 2002). Závodská *et al.* (2003) used polyclonal anti-*Antheraea* PTTH antibodies in an immunohistochemical survey of the central nervous systems of 12 species of insects in

10 orders: Archaeognatha, Ephemerida, Odonata, Orthoptera, Plecoptera, Hemiptera, Coleoptera, Hymenoptera, Tricoptera, and Diptera. Positive signals were seen in all species surveyed except *Locusta migratoria* (Orthoptera), with immunoreactive cells found mainly in the protocerebrum and less commonly in the subesophageal ganglion (the mayfly *Siphlonurus armatus* (Ephemerida) and the damselfly *Ischnura elegans* (Odonata)). The number of putative PTTH-containing cells ranged from two or three pairs (Archaeognatha, Hemiptera, and Hymenoptera) to five or more pairs (Plecoptera, Coleoptera, Tricoptera, and Diptera) and only in the stonefly *Perla burmeisteriana* (Plecoptera) a signal was detected in a potential neurohemal organ, the corpus cardiacum. These results are intriguing but must be interpreted with caution, pending further information such as determination of the size of the recognized protein or the immunoprecipitation of PTTH activity by the antibody. In this context, results obtained with an anti-*Manduca* PTTH antibody must serve as a cautionary tale. This monoclonal antibody recognized only a small number of cells in the CNS, including but not limited to the demonstrated prothoracicotropes (Westbrook *et al*., 1993), and apparently also bound to active PTTH (Muehleisen *et al*., 1993). Yet, the protein isolated by an immunoaffinity column constructed with this antibody proved to be an intracellular retinoid-binding protein (Mansfield *et al*., 1998) and not a secreted neurohormone.

3.2.2.3. Sequence Analyses and Comparisons of PTTHs

The amino acid sequence and structure of *Bombyx* PTTH have been characterized in a number of studies, beginning with Kataoka *et al*. (1987). **Figure 1** summarizes the major features of this protein. *Bombyx* PTTH appears to be synthesized as a 224-amino acid prohormone that is cleaved to yield an active peptide of 109 amino acids (Kawakami *et al*., 1990). The first 29 residues comprise a relatively hydrophobic region that is terminated by a trio of basic amino acids and fulfill the criteria defining a signal peptide. A second trio of basic residues immediately precedes the beginning of the mature PTTH hormone. Both these basic areas were believed to define peptide cleavage sites. Between these two sites lies a pair of basic amino acids that has been hypothesized to be an additional cleavage site (Kawakami *et al*., 1990). The presence of these three potential peptide processing sites has led to speculation that the region between the signal peptide and the mature PTTH sequence might be cleaved into two smaller peptides and that these small molecules serve a physiological function, such as modulating juvenile hormone synthesis in the corpus allatum (Kawakami *et al*., 1990; Ishizaki and Suzuki, 1992). However, there were no experimental data to support this speculation and this is still the case today.

A dimeric structure for *Bombyx* PTTH was long suspected and this was confirmed as part of the massive PTTH purification study that resulted in the determination of almost the entire amino acid sequence (Kataoka *et al*., 1991). This study also indicated that PTTH was a homodimer joined by one or more disulfide bonds and that asparagine-linked glycosylation (see **Figure 1**) was a likely cause for the disparity between the observed monomer MW of ≈17 kDa and the predicted MW of ≈12 700 (Kawakami *et al*., 1990). Further elucidation of the structure of *Bombyx* PTTH was provided by the incisive work of Ishibashi *et al*. (1994). This group used enzyme digestions of partially reduced recombinant PTTH to determine the intra- and interdimeric disulfide bonds (see **Figure 2**). This recombinant PTTH, expressed in bacteria (*Escherichia coli*) without glycosylation, had about 50% of the biological activity per nanogram of native PTTH. This result indicated that glycosylation is not necessary for biological activity although it may be required for maximum activity. *Bombyx* and other lepidopteran PTTHs (see below) do not have any significant homologs among vertebrate proteins, based on amino acid sequence (Kawakami *et al*., 1990; R. Rybczynski, unpublished BLAST analysis of vertebrate protein data bases.) However, Noguti *et al*. (1995) have shown that *Bombyx* PTTH exhibits an interesting arrangement of its intramonomeric disulfide bonds that is very much like that seen in some members of the vertebrate growth factor superfamily (βNGF, TGF-β2, and PDGF-BB). These workers suggest that PTTH is, in fact, a member of this superfamily and that PTTH and vertebrate growth factors share a common ancestor. It must be pointed out, however, that some insects, i.e., *Drosophila*, also possess genes belonging to the growth factor superfamily, such as *tolloid* and *60A*, with a significant amino acid identity to the vertebrate proteins in addition to the cysteine/disulfide bond conservation (Sampath *et al*., 1993). Furthermore, the intracellular signaling events activated by vertebrate growth factors like TGF-β, NGF, and PDGF are considerably different than those elicited by PTTH (see Section 3.2.3.4), involving receptors that are also kinases and that trigger quite different ligand-dependent intracellular processes (see Massagué, 1998; Haluska and Adjei, 2001; Huang and Reichardt,

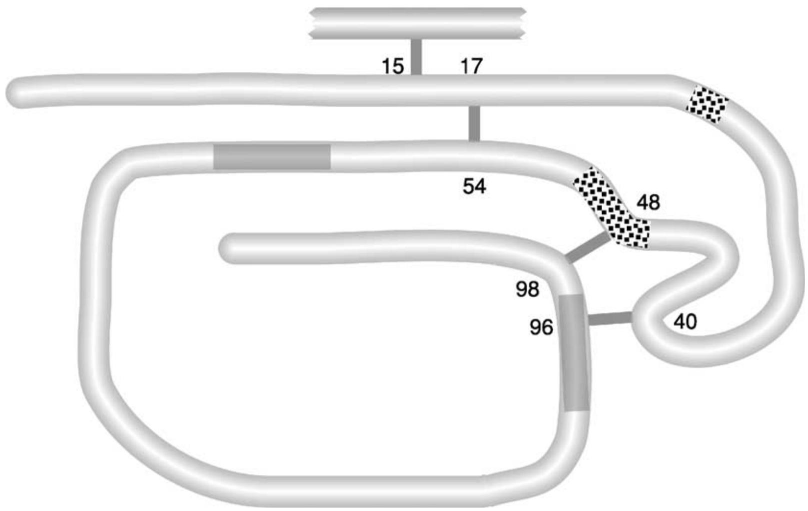

Figure 2 The structure of mature PTTHs, based on the *Bombyx* structure elucidated by Ishibashi *et al.* (1994). Dark shading indicates regions predicted to be hydrophobic in all five lepidopteran sequences while stippling indicates regions predicted to be hydrophobic in three lepidopteran sequences (Rybczynski, unpublished data). Numbers indicate the positions of the cysteines involved in intra- and intermonomeric bonds, in the mature *Bombyx* PTTH sequence.

2003). Thus, if PTTHs are members of the vertebrate growth factor superfamily, they have diverged extensively in amino acid sequence from other insect members of that superfamily. Furthermore, the coevolved events that PTTH initiate in their target cells would have to have diverged just as drastically from their vertebrate and insect counterparts. Perhaps resolution of this interesting puzzle will come from genomic studies of invertebrates more primitive than insects. In this regard, it is salient that the genome of the nematode *Caenorhabditis elegans* contains identifiable homologs to TGF proteins, e.g., *daf-7* (Inoue and Thomas, 2001), but appears to contain no gene coding for a PTTH-like protein (R. Rybczynski, unpublished data).

The amino acid sequences of the five lepidopteran PTTHs discussed above and of two dipteran candidate PTTHs are shown in **Figure 3**. The two dipteran sequences were found by searching the *D. melanogaster* and *A. gambiae* genomes with the complete *Bombyx* PTTH amino acid sequence. At present, no experimental data are available to indicate the function(s) of either of these two dipteran proteins and they are included here not only because of their general, although low, sequence identity and similarity with the lepidopteran PTTHs but, more particularly, because of the conservation of cysteine residues, i.e., it seems likely that these proteins are structurally similar to the demonstrated PTTHs. Note that due to the dynamic state of the *Anopheles* genome sequencing project at the time of writing (2003), the *Anopheles* sequence included here is undoubtedly incomplete and will be subject to revision. This may also be true of the candidate *Drosophila* sequence, although to a lesser extent.

All five lepidopteran PTTHs appear to be synthesized as prohormones that begin with a hydrophobic signal peptide sequence. The *Drosophila* protein is shown with a possible signal peptide sequence (**Figure 3**) but this region does not unequivocally meet the criteria for a cleaved signal peptide as defined by Nielsen *et al.* (1997). Following the signal peptide, these proteins exhibit only moderate sequence identity until an area preceding the mature PTTH sequence by about 35 amino acids. This cluster of greater amino acid conservation among the lepidopteran PTTHs might indicate that this region of the prohormone indeed has a function, as proposed by Ishizaki and Suzuki (1992). Note that the position of basic amino acids between the signal peptide and the mature hormone is not identical among the lepidopteran PTTHs and thus the 2 Da and 6 kDa peptide regions hypothesized for *Bombyx* (Kawakami *et al.*, 1990) do not have equivalents in *Samia*, *Antheraea*, and *Hyalophora*. A variety of proprotein convertases exist that recognize a variety of monobasic, dibasic, and tribasic amino acid patterns as well as specific sites lacking basic amino acids (see Loh *et al.*, 1984; Mains *et al.*, 1990; Seidah and Prat, 2002). Without experimental evidence, it is premature to predict where the preproPTTHs might be cleaved, in addition to the known site yielding the mature monomeric unit. The cellular location for the processing of PTTH from the longer, initial translation product to the shorter mature peptide form is not definitively

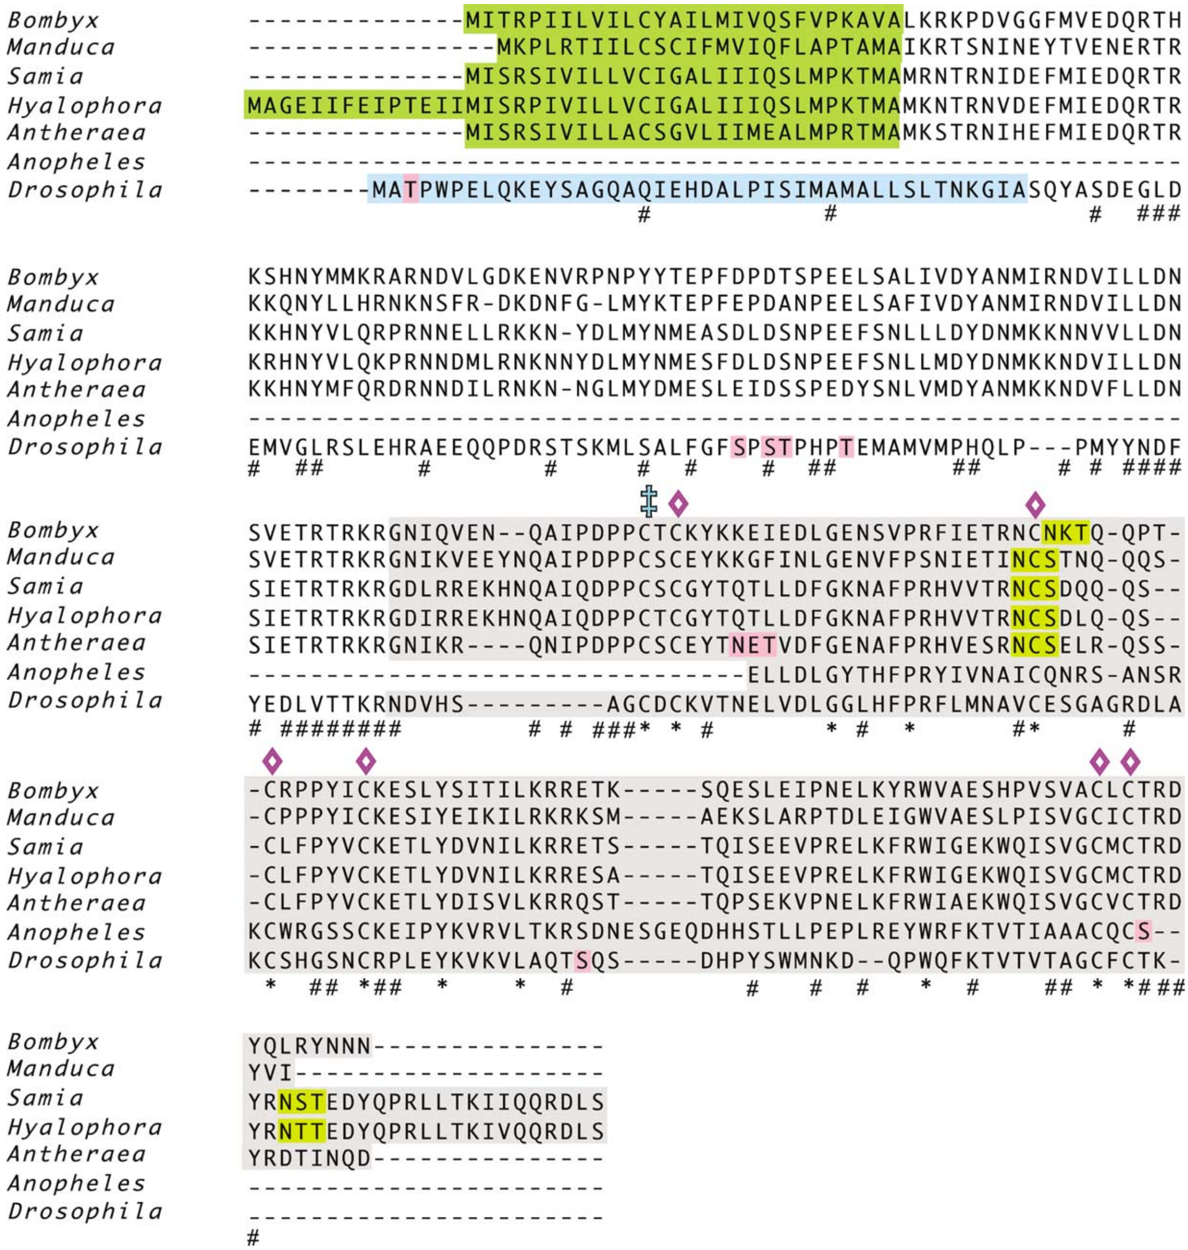

Figure 3 Sequence alignment of demonstrated and putative (*Drosophila*, *Anopheles*) PTTHs. Predicted signal peptide sequences are shaded with green. The low-probability *Drosophila* signal peptide is shaded with blue. Gray shading: the known or predicted mature PTTH sequences. #, amino acids conserved in all lepidopteran PTTHs; ∗, amino acids conserved in all PTTH sequences; ‡, cysteine participating in dimeric bonding; ◇, cysteines involved in intramonomeric bonds; yellow shading, predicted sites for *N*-linked glycosylation; magenta shading, potential sites for *O*-linked glycosylation. *N*-linked and *O*-linked glycosylation sites were predicted using the NetNGlyc 1.0 Server, the NetOGlyc 2.0 Server and the YinOYang 1.2 Server provided by the Center for Biological Sequence Analysis at the Technical University of Denmark.

known. Immunoblots of *Bombyx* and *Manduca* brain proteins revealed only the mature form, indicating that the protein is probably cleaved totally within the confines of the brain (Mizoguchi *et al.*, 1990; Rybczynski *et al.*, 1996). These observations did not reveal the intracellular site of processing, i.e., discern whether the cleavage(s) occurred completely within the soma or if cleavage occurred within axonal secretory granules, before those axons left the brain (see Loh *et al.*, 1984). It is presumed that removal of the signal sequence involves co-translational processing and takes place in the soma (see Loh *et al.*, 1984). The expected location of PTTH in neurosecretory particles has been

confirmed by immunogold electron microscopy in both *Manduca* and *Bombyx*, using the same anti-*Bombyx* PTTH antibody (Dai *et al.*, 1994, 1995).

The mature lepidopteran PTTHs begin with glycine-asparagine (GN) or glycine-aspartic acid (GD) in the lepidopteran PTTHs and the sequence from this glycine to the carboxy end has been confirmed to possess ecdysteroidogenic activity directly (*in vitro* prothoracic gland assays) in *Bombyx* (Kawakami *et al.*, 1990) and *Manduca* (Gilbert *et al.*, 2000), and indirectly (development of debrained pupae) in *Antheraea* (Sauman and Reppert, 1996a). Proteins beginning with glycines can be modified by N-terminal myristylation, yielding a hydrophobic moiety that often serves as a membrane anchor. No evidence for this or any other N-terminal or C-terminal posttranslational modifications were found during the sequencing of *Bombyx* PTTH (Kataoka *et al.*, 1991) and the derived sequences of the PTTHs do not begin or end with the amino acids most likely to be so modified, e.g., N-terminal alanines (methylation site) or serines (acetylation site) or C-terminal glycines (amidation substrate). The mature PTTH peptides all contain seven cysteines, except for the putative *Anopheles* sequence, which is preliminary and probably incomplete (Figure 3). Given the close spacing similarity among the sequences, it is likely that all PTTHs are linked by disulfide bonds and folded in the same manner as demonstrated for *Bombyx* PTTH (Ishibashi *et al.*, 1994; see Figure 2). The lepidopteran PTTHs also all contain consensus sites for *N*-linked glycosylation (Figure 3). Given a consistent disparity of 4000–5000 between molecular weights predicted by amino acid sequence versus larger molecular weights observed after SDS-PAGE, it seems likely that all five of these proteins are indeed glycosylated (for *Bombyx* compare Kawakami *et al.*, 1990 and Kataoka *et al.*, 1991; for *Manduca* compare Rybczynski *et al.*, 1996 and Shionoya *et al.*, 2003; for *Antheraea* see Sauman and Reppert, 1996a). The candidate *Drosophila* PTTH amino acid sequence does not contain a consensus site for *N*-linked glycosylation but does possess several for *O*-linked glycosylation (see Figure 3). Note that sites for *O*-linked glycosylation are difficult to predict and that only one of the potential sites in the *Drosophila* sequence falls within the putative mature peptide region. The processed (mature) PTTH sequences are, on the whole, hydrophilic proteins, with three or four short hydrophobic regions, depending on the species. Figure 2 shows a diagrammatic representation of the location of these hydrophobic regions in the lepidopteran sequences. Whether or not these hydrophobic regions play significant roles in determining monomeric or dimeric structures, or participate in receptor interactions are unanswered questions.

Table 1 summarizes the amino acid identities and similarities for pair-wise comparisons between six of the seven mature PTTH sequences presented in Figure 3; the candidate *Anopheles* sequence is omitted from the analysis due to the preliminary nature of the data. The similarities of these PTTH sequences are summarized graphically in Figure 4, using a phylogenetic tree neighbor-joining program (Saitou and Nei, 1987) applied to the mature PTTH amino acid sequences. In this analysis, the three Saturnid moths (*Antheraea*, *Hyalophora*, and *Samia*) form a clear-cut group, as do the two dipterans; *Bombyx* and *Manduca* form an outlier group in which the relationship of the two PTTH sequences do not closely match the conventional view of their taxonomic relationship. If the same analysis is performed with the prohormone rather than mature PTTH sequences, the results are essentially the same, reflecting the very similar, albeit modest, degrees of amino acid identity and similarity in the mature and prohormone sequences (see Table 1). The *Hyalophora* and *Samia* sequences are intriguingly similar and it would be very interesting to test if the PTTHs of these two species would significantly cross-activate prothoracic gland ecdysteroid synthesis. Such a comparison might

Table 1 Comparison of the amino acid identities and similarities for mature (bioactive) PTTHs

	Bombyx	Antheraea	Samia	Manduca	Hyalophora	Drosophila
Bombyx (224)[a]	X	52%[b] (75%)[c]	55% (73%)	59% (76%)	54% (73%)	22% (34%)

enable some informed speculation as to the location of the receptor-binding regions of PTTHs.

Two additional lepidopteran PTTHs have been cloned recently from the closely related species *Heliothis virescens* (Xu and Denlinger, 2003) and *Heliocoverpa zea* (Xu *et al*., 2003). The deduced amino acid sequences of these two PTTHs revealed that the major features of lepidopteran PTTHs, as discussed above, are conserved in these two new sequences, e.g., the proteolytic site yielding the mature peptide and the number and position of the seven conserved cysteines. Comparison of the deduced amino acid sequences of the mature peptide indicated that the *Heliothis* and *Heliocoverpa* are very similar (94% identity) but the identity with other lepidopteran PTTHs is much lower (48–59%) (Xu *et al*., 2003).

3.2.2.4. Are PTTHs Species Specific?

With amino acid identities and similarities averaging around 50% and 80%, respectively, it is difficult to predict *a priori* whether PTTHs should act across species at biologically meaningful concentrations. Actual tests for cross-species bioactivity have been equivocal on this question. Agui *et al*. (1983) tested three lepidopteran pupal brain extracts with prothoracic glands from the three species *M. sexta*, *M. brassicae*, and *B. mori*. Their data suggested that conspecific PTTHs were generally most efficacious at eliciting ecdysteroid synthesis but that heterospecific PTTHs were also effective at doses (brain equivalents) from one half to about four times that of the conspecific molecule. This study was not able to take into account possible interspecific differences in endogenous PTTH levels and the brain extracts employed had not been size-selected to remove small PTTH or bombyxin (see Section 3.2.2.5). Several studies have re-examined the issue of potential *Manduca–Bombyx* PTTH cross-species activation of ecdysteroidogenesis. Gray *et al*. (1994) and Rybczynski, Mizoguchi and Gilbert (unpublished data) did not find activation of *Manduca* ecdysteroidogenesis by crude, native (size-selected) or by recombinant (pure) *Bombyx* PTTH, respectively. Additionally, *Manduca* crude PTTH was not able to activate *Bombyx* prothoracic glands in an *in vivo* dauer assay (Ishizaki quoted in Gray *et al*., 1994). Similarly, *Bombyx* crude PTTH did not stimulate development by debrained *Samia* pupae, when separated from the much smaller bombyxin molecule originally thought to be PTTH (Ishizaki *et al*., 1983b; see also Kiriishi *et al*., 1992) and *Antheraea* recombinant PTTH did not activate *Manduca* prothoracic glands *in vitro* (Rybczynski and Gilbert, unpublished data).

Yokoyama *et al*. (1996) tested brain extracts prepared from pupal day 0 brains of four species of swallowtail butterflies (*Papilio xuthus*, *P. machaon*, *P. bianor*, and *P. helenus*) and found cross-specific activation of prothoracic gland ecdysteroid synthesis *in vitro*, with similar doses for half-maximal and maximal activation being relatively independent of the species of origin. These results are somewhat in contrast to the moth cross-species studies discussed above and this difference may be a function of the evolutionary closeness of the *Papilio* species versus the evolutionary distance of the moth species.

The possibility of cross-species PTTH activity has also been examined using dipteran ring glands and brain extracts. Roberts and Gilbert (1986) found that ecdysteroid synthesis by ring glands from post-feeding larval *Sarcophaga bullata* was readily activated by extracts from *Sarcophaga* prepupal brains and that these ring glands were not activated by *Manduca* brain extract. In contrast, *Manduca* prothoracic glands showed a stage-specific response to *Sarcophaga* brain extract, with larval but not pupal glands responding positively at relatively low doses of extract, i.e., less than one brain equivalent. Henrich (1995) addressed the cross-species question with studies on the *Drosophila* ring gland. As discussed above, the activation of *Drosophila* ring gland ecdysteroidogenesis by *Drosophila* brain or ganglionic extracts is not robust. Nevertheless, in a small study, Henrich (1995) found that both small and large *Manduca* PTTH preparations were able to elicit increased steroidogenesis by the ring gland with the former possibly being more efficacious. In contrast, a preliminary study with pure recombinant *Manduca* PTTH was not able to detect stimulation of *Drosophila* ecdysteroid synthesis (Rybczynski, unpublished data).

Both *Rhodnius* and *Bombyx* have served as important experimental organisms in research aimed at understanding PTTH. Vafopoulou and Steel (1997) have explored the effect of *Bombyx* PTTH on ecdysteroid synthesis by *Rhodnius* prothoracic glands under *in vitro* conditions. They found that recombinant *Bombyx* PTTH elicited a statistically significant increase in ecdysteroidogenesis relative to controls, with effective concentrations similar to that observed in *Bombyx*–*Bombyx* experiments. This is an intriguing and surprising result, given the evolutionary distance between *Rhodnius* (Hemiptera) and *Bombyx* (Lepidoptera). A puzzling feature of the results is the very sharp optimum in concentration seen with the *Bombyx* PTTH ($8\,ng\,ml^{-1}$), with decreasing response seen at $10\,ng\,ml^{-1}$ and above, although a similar, albeit broader, optimum is also seen with *Rhodnius* brain extracts (Vafopoulou *et al*., 1996). Also of note is the approximately two-fold increase in ecdysteroid synthesis achieved with *Bombyx* PTTH-stimulated *Rhodnius* glands under the same conditions with which *Rhodnius* brain extract elicited nearly a five-fold increase (*cf*. Vafopoulou *et al*., 1996; Vafopoulou and Steel, 1997). Thus, care must be exercised in interpreting these data, especially given observations in *Manduca* that small increases in ecdysteroid synthesis can be obtained with nonspecific stimuli (Bollenbacher *et al*., 1983).

In summary, the question of PTTH species specificity remains open. The cloning, sequencing and expression of recombinant pure PTTHs will offer a more rigorous tool to investigate this topic and perhaps by doing so, gain insight into the portion of PTTH that productively interacts with PTTH receptors. If the region that contacts the receptor appears to be relatively small, then chimeric recombinant PTTHs can be used to investigate ligand-receptor interactions. At present, it seems premature to speculate on which portion(s) of the PTTH protein are necessary and sufficient for binding to the PTTH receptor and whether the area(s) that confer species-specificity are congruent with the former sites. It does seem likely that the most N-terminal region of the mature PTTH molecule is not involved in receptor binding since an antibody to this region failed to block PTTH-stimulated ecdysteroid synthesis by *Manduca* prothoracic glands (Rybczynski *et al*., 1996). If sequence divergence is any guide to areas conferring species-specificity and receptor binding, then one region of interest can be pointed out (considering only the lepidopteran species), i.e., an area between a conserved triplet of basic amino acids and a conserved serine that is located slightly past the middle of the mature peptide (see fourth of the five sets of rows in **Figure 3**). This area is also a hydrophilic region but as might be expected for a peptide hormone released into an aqueous environment, most of the mature PTTH peptide is predicted to be hydrophilic. Note that this region lies outside the common fold area that sequence-based modeling indicated that PTTH might share with members of the vertebrate growth factor superfamily (Noguti *et al*., 1995). Note also that this PTTH region is not positionally equivalent to the regions of the platelet-derived growth factor (PDGF) or brain-derived neurotrophic factor (BDNF) molecules, for example, that are believed to be crucial for receptor interaction (LaRochelle *et al*., 1992; O'Leary and Hughes, 2003); however, like the regions in these vertebrate molecules, this portion of the PTTH molecule lies in an area predicted to be within a hydrophilic area, extending out from the common fold area (Noguti *et al*., 1995).

3.2.2.5. Bombyxin and Small PTTH

The small neuropeptide bombyxin was initially characterized as *Bombyx* PTTH, using a *Samia* assay, until it was found that purified bombyxin was ineffective at stimulating ecdysteroid synthesis in *Bombyx* itself (see Section 3.2.2.1). The purification and amino acid sequencing of bombyxin, which began when it was considered to be *Bombyx* PTTH, revealed that there was actually a family of bombyxin proteins with sequence homology to the A and B chains of human insulin (see Ishizaki and Suzuki, 1994). Jhoti *et al*. (1987) modeled the three-dimensional structure of a bombyxin and found that it could assume an insulin-like tertiary structure. Despite these sequence and structural similarities, the functions of bombyxins, with nearly 40 genes in *Bombyx* (Kondo *et al*., 1996), remain practically unknown. Specific receptors in lepidopteran ovarian cells have been identified, suggesting a role in reproduction (Fullbright *et al*., 1997). Roles in ovarian and embryonic development have also been suggested (Orikasa *et al*., 1993; Tanaka *et al*., 1995). Whether or not ovarian ecdysteroid synthesis might be affected is an unaddressed question. Evidence also exists that a bombyxin may function in carbohydrate metabolism, in an insulin-like manner (Satake *et al*., 1997; Masumura *et al*., 2000). Recent work by Nijhout and Gunnert (2002) has demonstrated another role for a bombyxin in the butterfly *Precis coenia*. In this species, bombyxin II acts as a growth factor in concert with 20-hydroxyecdysone, stimulating cell division in cultured wing imaginal discs.

Finally, in regard to bombyxin, the ability of *Bombyx* bombyxin, effective at 30 pM, to stimulate adult development in debrained *Samia* pupae is still not understood (see Ishizaki and Suzuki, 1994). Nagata *et al.* (1999) used the deduced amino acid sequence of two *Samia* bombyxin homologs to synthesize the corresponding peptides. These peptides were then used in the *Samia* debrained pupae, where they proved to be effective at stimulating adult development at estimated hemolymph concentrations of 1–5 nM, a concentration at least 30 times higher than the *Bombyx* bombyxin. Given the plethora of bombyxin genes in *Bombyx*, and presumably other Lepidoptera, the possibility that one of these genes might code for a true prothoracicotropic protein cannot be ruled out. An additional factor must be kept in mind when considering bombyxins, i.e., the ability of bombyxins to activate adult development does not prove that bombyxins directly stimulate prothoracic gland ecdysteroidogenesis. In addition to the study by Kiriishi *et al.* (1992), demonstrating the relative ineffectiveness of bombyxin in stimulating ecdysteroid synthesis by isolated prothoracic glands (see Section 3.2.2.1), Vafopoulou and Steel (1997) found that *Bombyx* bombyxin was much less effective than *Bombyx* PTTH at stimulating ecdysteroid synthesis by *Rhodnius* glands *in vitro*. Other tests *in vitro* of small ecdysteroidogenic molecules have used large amounts of size-fractionated brain extracts, e.g., 50 brain equivalents per prothoracic gland, making it difficult to determine the physiological relevance of the stimulatory molecules, presumed to be bombyxins (Endo *et al.*, 1990; Fujimoto *et al.*, 1991).

What role insulin-like factors play in the acute regulation of steroidogenesis in taxa other than the Lepidoptera is also an open question. The *Drosophila* genome does not appear to contain any definite bombyxin homologs (R. Rybczynski, unpublished BLAST analysis), but it does contain seven genes that, like the bombyxins, code for proteins containing characteristic insulin motifs (Brogiolo *et al.*, 2001). These seven genes (*Drosophila* insulin-like proteins: DILP 1–7) do not show significant homology to bombyxins outside of the insulin motifs and, unlike the bombyxins, are not limited in expression to neuronal cells (Brogiolo *et al.*, 2001). It is not known if any of the DILP gene products participate in regulating ecdysteroidogenesis.

Despite the demonstration that the so-called small PTTH of *Bombyx*, now known as bombyxin, is very unlikely to be a physiologically important PTTH in this species, the question persists – is there more than one brain-derived PTTH? As discussed above (Section 3.2.2.2), size-fractionated brain extracts frequently exhibit two peaks of ecdysteroidogenic activity, with one peak at 20 000–30 000 MW and a second, smaller peak below 10 000 MW. In most cases, there are simply no data beyond approximate molecular weight and dose (brain equivalents) that can address this question. The observations indicate a much larger dose requirement for the so-called small PTTHs. Additionally, a smaller maximum response (e.g., Endo *et al.*, 1990, 1997; Yokoyama *et al.*, 1996) suggests, but does not prove, that these so-called small PTTHs may be bombyxin homologs; as noted for *Bombyx* prothoracic glands tested *in vitro* (Kiriishi *et al.*, 1992), PTTH stimulated ecdysteroidogenesis much more effectively than did bombyxin. However, there are some data from *Manduca* that suggest that small PTTH in this species may be a molecule other than a bombyxin. Bollenbacher *et al.* (1984) described a small PTTH (MW = 6–7 kDa) that has subsequently been partially characterized in regard to its developmental expression and the signal transduction events it elicits in prothoracic glands. *Manduca* small PTTH appears to be much more abundant in pupal than in larval brains, while “big” PTTH shows only a slight increase in the pupal versus larval brain (O’Brien *et al.*, 1986). Bollenbacher *et al.* (1984) reported that small PTTH was notably less effective at stimulating ecdysteroid synthesis in pupal prothoracic glands than in larval glands; however, a study by O’Brien *et al.* (1986) showed no such difference. Like big PTTH (see Section 3.2.3.4), *Manduca* small PTTH appears to stimulate ecdysteroid synthesis via Ca^{2+} influx and Ca^{2+}-dependent cAMP accumulation (Watson *et al.*, 1993; Hayes *et al.*, 1995). These observations concerning intracellular signaling suggest that *Manduca* small PTTH might not be a bombyxin homolog because, as members of the insulin peptide family, bombyxin would not be expected to stimulate either Ca^{2+} influx or Ca^{2+}-dependent cAMP (see Combettes-Souverain and Issad, 1998). However, this is an inference as authentic bombyxin-stimulated intracellular events do not appear to have been studied. It should also be pointed out that for small PTTH to have the same effects as PTTH on Ca^{2+} influx and Ca^{2+}-dependent cAMP generation is surprising and confusing, especially if small PTTH does not differentially activate larval glands (*cf.* conflicting data in Bollenbacher *et al.*, 1984 and O’Brien *et al.*, 1986). In fact, it has been hypothesized that small PTTH might be an active proteolytic fragment of PTTH (Gilbert *et al.*, 2002); if so, it is unclear whether small PTTH is generated as an artifact during PTTH extractions, or is a naturally occurring processed form.

Besides bombyxin and *Manduca* small PTTH, other, noncerebral, ecdysiotropic activities have been described, e.g., factors extracted from the proctodaea of *Manduca*, the European corn borer, *Ostrinia nubilalis*, and the gypsy moth, *L. dispar* (Gelman *et al.*, 1991; Gelman and Beckage, 1995). These data are not completely surprising, given the precedent of the vertebrate gut as an endocrine organ. However, a definitive role for such factors *in vivo* has not been established and further discussion of these candidate ecdysiotropes is outside the scope of this review.

3.2.3. Prothoracicotropic Hormone: Synthesis and Release

3.2.3.1. Sites of Synthesis and Release

Agui *et al.* (1979), using micro-dissections, demonstrated functionally that *Manduca* PTTH was present only in two pairs of dorsolateral brain neurosecretory cells. Subsequently, a number of lepidopteran PTTHs have been purified and/or cloned and antibodies raised against the derived sequences (see Section 3.2.2.1). The use of cDNA probes for *in situ* localization of these PTTH mRNAs supported the findings of Agui *et al.* (1979) in all species tested (*Bombyx*: Kawakami *et al.*, 1990; *Antheraea*: Sauman and Reppert, 1996a; and *Manduca*: Shionoya *et al.*, 2003). Similarly, the use of antibodies in immunohistochemical studies also supported the early *Manduca* work (*Bombyx*: Mizoguchi *et al.*, 1990; *Antheraea*: Sauman and Reppert, 1996a; and *Manduca*: Gilbert *et al.*, 2000) (see **Figure 5**). Of particular note was the co-localization of PTTH mRNA and protein to the same cells in *Antheraea* brain (Sauman and Reppert, 1996a). This co-localization has been assumed to be true but has only been explicitly demonstrated in *Antheraea*.

Figure 5 Immunocytochemical localization of PTTH in the pupal brain of *Manduca sexta* showing that PTTH is detectable only in the cell bodies and axons of two pairs of lateral neurosecretory cells. Scale bar = 100 μm. (Data from Gilbert, L.I., Rybczynski, R., Song, Q., Mizoguchi, A., Morreale, R., *et al.*, **2000**. Dynamic regulation of prothoracic gland ecdysteroidogenesis: *Manduca sexta* recombinant prothoracicotropic hormone and brain extracts have identical effects. *Insect Biochem. Mol. Biol. 30*, 1079–1089.)

The antibody studies discussed above were conspecific studies, e.g., an anti-*Bombyx* PTTH antibody was used to probe *Bombyx* tissues. However, as discussed in Sections 3.2.2.1 and 3.2.2.2, anti-PTTH antibodies have been used also in heterospecific immunohistochemical studies. Anti-*Bombyx* PTTH antibodies were used to probe *Manduca* (Dai *et al.*, 1994), *Samia* (Yagi *et al.*, 1995), *D. melanogaster* (Žitňan *et al.*, 1993), and *Locusta* (Goltzene *et al.*, 1992). In *Manduca* and *Samia* brains, the antibody decorated two pairs of lateral neurosecretory cells. These cells appeared to be the same as seen in *Bombyx* brain, in the conspecific probing summarized above. In *Drosophila*, Žitňan *et al.* (1993) found that the anti-*Bombyx* PTTH bound to two superior mediolateral cells that might be equivalent to the lepidopteran PTTH-positive cells. Also positive were axons and axon terminals in the neurohemal region of the ring gland, as to be expected based on the site of PTTH release determined in Lepidoptera. However, a number of additional cells in the subesophageal thoracic and abdominal ganglia were also positive, particularly in the adult. It is unknown if this last result indicates multiple sites of PTTH synthesis or a cross-reactivity to a protein besides PTTH.

PTTH immunoreactivity in *Locusta* is dependent on the antibody employed. Goltzene *et al.* (1992) found that a number of brain neurosecretory-type cells reacted positively with an anti-*Bombyx* PTTH antibody while the use of an anti-*Antheraea* PTTH antibody revealed no positive reactions (Závodská *et al.*, 2003). This same anti-*Antheraea* PTTH antiserum was used to survey a wide variety of insects (Závodská *et al.*, 2003: see Section 3.2.2.2); until we know more about the nature of PTTH in these species, it is not possible to interpret the smorgasbord of immunohistochemical patterns seen among the surveyed taxa.

Functional evidence that the corpus allatum and not the corpus cardiacum was the neurohemal organ for lepidopteran PTTH was provided by Agui *et al.* (1979, 1980) and Carrow *et al.* (1981) and immunohistochemical studies have supported this conclusion (Mizoguchi *et al.*, 1990; Dai *et al.*, 1994). If the additional immunohistochemically positive cells seen in some studies (e.g., Žitňan *et al.*, 1993, Závodská *et al.*, 2003) actually do contain PTTH,

it is presumably synthesized and released there. Further discussion of these "outlier" cells awaits confirmation that the regions of interest contain bioactive PTTH.

3.2.3.2. Control of Release: Neurotransmitters

PTTH release is apparently ultimately controlled by a number of factors, including photoperiod, size and nutritional state of the animal (see Section 3.2.1). Proximately, a number of studies have pointed out the likelihood that PTTH release is directed by cholinergic neurons synapsing with the prothoracicotropes. It must be emphasized that the data discussed in this section in the following studies do not definitively identify PTTH as the active molecule released from the brain, although this is most likely the case.

Carrow *et al.* (1981) showed that PTTH could be released by depolarizing *Manduca* (brain) neurons with a high potassium concentration in the presence of Ca^{2+}; a similar result was obtained when *Bombyx* brains were treated with high K^{+} in the presence or absence of external Ca^{2+}. Lester and Gilbert (1986, 1987) found that acetylcholine accumulation and α-bungarotoxin binding sites exhibited temporal peaks in the brain of fifth instar *Manduca* larvae and that these peaks coincided with periods of PTTH release and increased ecdysteroid synthesis. Of course, it is not likely that all the changes in the cholinergic systems of the brain that occur at these stages directly feed into the PTTH-producing neurons but these data are supportive for a role of cholinergic neurons in PTTH biology. Direct evidence that cholinergic stimulation can result in PTTH release comes from several *in vitro* studies of *Bombyx* and *Mamestra*. Agui (1989) showed that acetylcholine and cholinergic agonists caused cultured *Mamestra* brains to release PTTH into the medium while dopaminergic agents have little or no effect. Shirai *et al.* (1994) obtained similar results, using the acetylcholine agonist, carbachol, and further refined the analysis by using both muscarinic and nicotinic agents. They found that treatment with muscarine caused PTTH release from *Bombyx* brains *in vitro*, and that carbachol-induced release was blocked by the muscarinic antagonist atropine. Nicotine had no effect on PTTH release, with the composite data indicating the involvement of a muscarinic acetylcholine receptor. Later immunohistochemical studies revealed that the PTTH-producing cells of *Bombyx* do indeed express a muscarinic acetylcholine receptor (Aizono *et al.*, 1997). Shirai *et al.* (1994) further determined the effects of a calmodulin inhibitor, a phospholipase C inhibitor (PLC) and a protein kinase C (PKC) inhibitor on carbachol-induced PTTH release. All three drugs inhibited the effects of carbachol, suggesting roles for Ca^{2+}-calmodulin, PKC, and PLC in this system. A role for Ca^{2+} was more directly demonstrated, when it was found that Ca^{2+}-ionophore also caused PTTH release (Shirai *et al.*, 1995). Finally in regard to the cholinergic neurotransmission, Shirai *et al.* (1998) investigated the possible role for small G-proteins in carbachol-stimulated PTTH release. The poorly hydrolyzable GTP analog GTPγS was found to stimulate PTTH release in the presence of a PLC inhibitor; the use of the PLC inhibitor removed the positive effect that the GTPγS would have on the larger heterotrimeric G-protein directly associated with muscarinic receptors (see Hamilton *et al.*, 1995).

The experiments of Agui (1989) indicated that dopamine might have a small effect on PTTH release *in vitro*. This possibility was tested with *Bombyx* brains and it was found that dopamine and serotonin increased PTTH release, while norepinephrine had no effect (Shirai *et al.*, 1995). The effects of dopamine and serotonin were notably slower than that of carbachol, suggesting that the first two compounds might be acting at some distance from the PTTH-producing cells. It must be emphasized, though, that there are no data that demonstrate that cholinergic agonists directly act upon the prothoracicotropes.

In contrast to observations in *Bombyx* (Shirai *et al.*, 1995), serotonin had an inhibitory effect on PTTH release, as measured by prothoracic gland ecdysteroid synthesis, during short-term (3 h) co-cultures of cockroach (*Periplaneta americana*) brains and prothoracic glands (Richter *et al.*, 2000). No effect of serotonin on isolated prothoracic gland ecdysteroid synthesis was found. Serotonin is the precursor to melatonin, the latter playing an important role as neuromodulator associated with darkness in diel light/dark cycles. In contrast to the results with serotonin, Richter *et al.* (2000) found that melatonin increased PTTH release in brains and prothoracic gland co-cultures during both short-term (photophase) and long-term (12 h: scotophase) incubations. A melatonin receptor antagonist, luzindole, blocked the melatonin effect. Again, neither melatonin nor luzindole had an effect on prothoracic gland ecdysteroid synthesis in the absence of the brain. These results raise the possibility that melatonin may play a role in modulating temporal patterns of PTTH release. However, as Richter *et al.* (2000) pointed out, there was a lack of daily rhythmicity in the molting of cockroaches in their colony, suggesting that there was no rhythmicity to PTTH release either, thus indicating that an *in vivo* role for melatonin is problematic

(see Section 3.2.3.4 and **Chapter 3.11**) for further information on cycles of PTTH release).

3.2.3.3. Control of Synthesis and Release: Juvenile Hormone

Insect molts, be they simple or metamorphic, are under the general control of 20-hydroxyecdysone (20E). Of course, 20E does not act alone and there are additional hormones, like ecdysis-triggering hormone and eclosion hormone, that act downstream from 20E, playing very proximate roles in controlling ecdysis behavior (see Mesce and Fahrbach, 2002; and **Chapter 3.1**). However, juvenile hormones (JHs), which also participate in regulating molting and metamorphosis (see **Chapter 3.7**), modulate the action of 20E in a way that makes them partners with 20E rather than dependent factors (see **Chapter 3.8**). Juvenile hormones are epoxidated sesquiterpenoids produced in, and released from, the corpus allatum, which is also the site of PTTH release. Depending on the taxon and the developmental stage, a corpus allatum may synthesize one or two methylated JHs as well as JH acids (see Gilbert *et al*., 1996; Henrich *et al*., 1999; and **Chapter 3.7**).

JH is an important hormone in some aspects of insect reproduction (see Nijhout, 1994; and **Chapter 3.9**) but the relevant role of JHs, in regard to 20E and hence PTTH, is the ability of JHs to direct a molt either into a simple or into a metamorphic pathway. Basically, the presence of circulating JH during an ecdysteroid peak results in the next molt being a simple one, i.e., larva to larva, but if JH levels are very low during an ecdysteroid peak, then the ensuing molt will be a metamorphic molt, e.g., larva to pupa. In the last larval instar, of many or most insects, a small release of PTTH appears to trigger a small ecdysteroid release from the prothoracic gland during a period of very low JH titer. This small increase in ecdysteroid titer (Bollenbacher *et al*., 1981) is termed the commitment peak because it commits the animal to a metamorphic molt (Rid-Riddiford, 1976).

How JHs modulate molt quality is not well understood. A considerable number of studies have demonstrated that JH or JH analogs (JHAs) (see **Chapters 3.7** and **3.8**) have effects on ecdysteroid titers when applied topically, injected, or fed to preadult insects. In these studies involving intact larvae, pupae, debrained animals, or isolated abdomens, JHs appeared to modulate PTTH synthesis and/or release, and perhaps affected the PTTH signaling pathway in the prothoracic gland or the gland's capacity for ecdysteroidogenesis. Two periods of JH influence have been identified in such studies during the last larval instar; the influence of JH during the penultimate instar is different and is treated separately below.

In Lepidoptera, JH hemolymph titers decline dramatically in the first few days of the last larval instar (for *Manduca*, see Baker *et al*., 1987; for *Bombyx*, see Nimi and Sakurai, 1997). The JH decline is followed by a release of PTTH and the resultant small peak in the ecdysteroid titer termed the commitment peak (see Section 3.2.3.1). Application of juvenoids (JHs or JH analogs: JHAs) before the commitment peak results in a delay of development, e.g., deferral of the cessation of feeding and wandering (see Riddiford, 1994, 1996). In *Manduca*, Rountree and Bollenbacher (1986) found that prothoracic glands from early fifth instar larvae treated with JH-1 or ZR512 (a JHA) for 10 h prior to extirpation still responded to PTTH with increased ecdysteroid synthesis, although the normal developmental increase in basal ecdysteroidogenesis was inhibited. However, when the brain-retrocerebral complexes from such animals were implanted into head-ligated larvae, they exhibited a delay in activating development, relative to control complexes. This result suggested that JHs controlled the time of PTTH release at this time, although the data do not rule out an effect on PTTH content/synthesis in the complexes, as well. In a later study of *Manduca* glands, Watson and Bollenbacher (1988) did find a reduced response to PTTH *in vitro*, but this study involved animals treated with a JHA for 2 days, starting at an earlier time point. Thus, the conclusions reached may reflect the experimental paradigms as well as the animal's intrinsic biology.

In *Bombyx*, similar results have been obtained. Sakurai (1984), using the technique of brain removal, concluded that PTTH release occurred early in the fifth instar shortly after a precipitous decline in JH titer, as found for *Manduca*. Furthermore, allatatectomy late in the fourth instar shortened the phagoperiod in the fifth instar, and brain removal performed on these larvae at 48 h into the fifth instar did not block metamorphosis. Sakurai also found that JH application early in the fifth instar prolonged the larval period. The combined data suggested again that JH in the early fifth instar blocked PTTH release. Sakurai *et al*. (1989) provided evidence that JH inhibits prothoracic gland activity in *Bombyx* by showing that allatectomy of early fifth instar larvae accelerated the period of PTTH sensitivity in glands, but that this acceleration was blocked by JH treatment.

The above studies utilized either JHs, or JH analogs with JH-like chemical structures, i.e., terpenoids. However, the nonterpenoid chemical fenoxycarb, a carbamate, has also been shown to exhibit JH-like

effects when applied to larvae. Leonardi *et al.* (1996) found that single, topically applied doses of fenoxycarb, as low as 10 femtograms, were sufficient to disrupt larval–pupal ecdysis in *Bombyx*. Also studying *Bombyx*, Monconduit and Mauchamp (1998) showed that very low doses of fenoxycarb, 1 ng and below, were sufficient to induce permanent larvae when administered in the food during the phagoperiod of the last larval instar. This treatment also considerably depressed the ecdysteroid synthesis of prothoracic glands when measured *in vitro*. The glands still exhibited a qualitative response to a (crude) PTTH preparation, but the quantitative response was greatly curtailed. Dedos and Fugo (1996) found that fenoxycarb significantly and directly inhibited prothoracic gland steroidogenesis under *in vitro* conditions; however, the effective doses required in these *in vitro* experiments were much higher (0.5–1 μg/gland) than employed by Leonardi *et al.* (1996) and Monconduit and Mauchamp (1998). Thus, the possibility that fenoxycarb at these doses had effects not attributable to JH-like activities cannot be ruled out, as suggested by Mulye and Gordon (1993) and Leonardi *et al.* (1996), among others.

When exogenous JH or JH analogs are administered after the commitment peak period of last larval instars, quite different results are obtained, i.e., JHs accelerate development and shorten the period to pupation (see Sakurai and Gilbert, 1990; Smith, 1995). Brain removal or ligation after the commitment peak period does not affect this accelerative ability of JH, indicating that the brain and hence PTTH release are not the targets of JH at this time (Safranek *et al*., 1980; Gruetzmacher *et al*., 1984a). Intriguing in this regard are the observations of Sakurai and Williams (1989). They implanted prothoracic glands extirpated from feeding (day 2) fifth instar *Manduca* larvae into pupae lacking a cephalic complex. Treatment of these pupae with either 20E or the JH analog hydroprene resulted in an inhibition of steroidogenesis when the prothoracic glands were studied subsequently *in vitro*. However, if both 20E and hydroprene were administered, an increase in ecdysteroid synthesis was seen. These conditions simulate the postcommitment peak period in larvae, when JH (particularly JH acids) and 20E are both high. Thus, as Smith (1995) suggested, the prepupal ecdysteroid peak may be initiated by PTTH and maintained by JH, with the eventual decline of JH titer resulting in the decline of ecdysteroid levels that occurs shortly before larval–pupal ecdysis.

The relationship between JH and the brain-prothoracic gland axis observed in the last larval instar is not characteristic of every developmental stage. Stages prior to the last larval instar lack the commitment peak of ecdysteroids, along with the PTTH release that triggers it. In *Manduca*, the fourth (penultimate) larval instar is characterized by high to moderate JH levels throughout (see Riddiford, 1996; and **Chapter 3.7**). The fourth instar JH titer minimum is reached shortly before ecdysis to the fifth instar and ecdysteroid levels in the hemolymph begin rising while JH levels are relatively high, albeit falling. In *Bombyx*, the case is somewhat more complicated. Peaks in the JH titer occur during the early and in the middle to late portions of the penultimate instar, with the minimum between the two peaks being higher in concentration and shorter in duration than the minimum measured during the last (fifth) instar (Nimi and Sakurai, 1997).

Fain and Riddiford (1976) showed that head ligation of fourth instar *Manduca* larvae before a presumed head critical period resulted in precocious pupation; this operation isolated the sources of both PTTH and JH from the prothoracic glands. Injection of 20E immediately after ligation resulted instead in a larval molt. Delaying the 20E treatment resulted in a progressive loss of the larval response but JH injection maintained the 20E-induced larval molt. Lonard *et al.* (1996) found that application of the JH analog methoprene to fourth instar *Manduca* larvae affected neither the ecdysteroid titer *in vivo* nor the ecdysteroidogenic activity of prothoracic glands measured *in vitro*; however, allatectomy abolished the ecdysteroid peak, which could be restored by the application of methoprene. Further methoprene experiments with debrained and neck-ligated animals indicated that the restorative effect of methoprene involved the brain and was interpreted to indicate the existence of JH-dependent PTTH release.

Sakurai (1983) observed results in *Bombyx* similar to those obtained by Fain and Riddiford (1976), i.e., head ligation early in the fourth instar resulted in precocious pupation and application of methoprene shifted the postligation molts back to larval or larval–pupal intermediates. Unlike the case of JH in *Manduca*, methoprene was effective at reversing precocious pupations only when administered about 24 h after ligation, with larvae treated directly after ligation simply showing no further development. This difference between the two species may reflect a fundamental difference in the ecdysteroidogenic competence of the prothoracic gland in the time immediately following larval ecdysis (see Section 3.2.3.4). Sakurai also found that application of 20E to debrained *Bombyx*, still possessing corpora allata, resulted in larval rather than pupal molts.

These data from *Manduca* and *Bombyx* indicate that high levels of 20E in the relative absence of JHs will result in a pupal molt, even prior to the last larval instar. However, under ordinary circumstances, PTTH release and ecdysteroid synthesis take place against a significant JH titer background in stages other than the last larval instar.

The relationship between JHs and the PTTH-prothoracic gland axis during pupal–adult development has not been studied extensively, perhaps because there is no JH in early lepidopteran pharate adults, and therefore the experiments are not physiological. In general, application of exogenous juvenoids to pupae shortens the time until adult ecdysis, and the juvenoid must be administered about the time of pupal ecdysis or termination of pupal diapause (see Sehnal, 1983). Using *Bombyx*, Dedos and Fugo (1999a) injected the potent juvenoid fenoxycarb at pupal ecdysis and found that the ecdysteroids were considerably elevated above control during subsequent pupal–adult development. *In vitro* analysis of the prothoracic glands from treated animals showed elevated ecdysteroid secretion relative to controls; additionally, brain-retrocerebral complexes from fenoxycarb-treated animals secreted more PTTH than controls did, after 3 h of *in vitro* incubation; however, there was no difference from controls if the incubation was only 1 h. These data were interpreted to indicate that fenoxycarb stimulated ecdysteroid synthesis by promoting PTTH release. However, the observed delay in the fenoxycarb-facilitated increase in PTTH release *in vitro* could also be interpreted as a release from *in vivo* inhibition, once the brain-retrocerebral complexes were removed from the larvae.

Although all the studies cited above, and many others not discussed here, clearly point out the existence of cross-talk between the brain-prothoracic gland axis and juvenile hormones, considerable care must be exercised in interpreting these experiments. Ligations, extirpations, and tissue transplants have provided valuable insights into insect endocrinology over the years but these methodologies are rarely clean. For instance, allatectomy removes not only the site of juvenile hormone synthesis but also the neurohemal organ for normal PTTH release. Similarly, brain removal eliminates a source of many neuropeptides as well as a biochemical clock involved in regulating many diel cycles (see **Chapter 4.11**).

Experiments involving hormone additions to intact or nonintact animals also have to be interpreted carefully. Hormones are powerful drugs when given in large doses or at unusual times. For example, fenoxycarb-treated pupae that had elevated ecdysteroid titers also exhibited malformed rectums (Dedos and Fugo, 1999a) and whether or not this result tells us something informative about ecdysteroid titer regulation during normal adult development is open to debate. JH has often been suggested to have a negative effect on PTTH secretion in the last larval instar (see above) based on experiments in which larvae were treated with JH or JH analogs early in the instar. However, recently Mizoguchi (2001) measured the PTTH titer in JH-treated fourth and fifth instar *Bombyx* larvae, using time-resolved fluorimmunoassay. His data showed that, in fact, JH treatment had just the opposite effect, i.e., JH treatment raised the PTTH hemolymph titer! Thus, experiments in which PTTH secretion was measured *in vitro* following JH treatment of the donor larvae appear to be misleading in an attempt to understand the relationship between JH and PTTH.

Differences between species in the basic intercellular or intracellular "wiring" of their endocrinological systems may also confound experimental manipulations. An obvious example is the variation among species in prothoracic gland innervation. *Manduca* and *Bombyx* glands appear not to be innervated while prothoracic glands in other species clearly are (see Section 3.2.5.4). Brain extirpation in the latter species could have consequences on the prothoracic gland beyond the obvious removal of the source of PTTH. Less obvious but potentially important are developmental differences between species that complicate the ability to make generalizations. For instance, during the earliest portion of the last larval instar, *Bombyx* prothoracic glands are refractory to PTTH stimulation while *Manduca* glands are responsive (Sakurai, 1983). This refractoriness stems from a developmentally specific deficit in PTTH receptors or some other very early-acting component of the PTTH signal transduction cascade (Gu *et al.*, 1996; see also Section 3.2.5.1).

It must also be emphasized that direct effects of JHs on prothoracic glands have been seen rarely, indicating the probable participation of one or more additional cell types and/or hormones and/or neuronal connections in JH effects. In the rare cases where a direct effect has been demonstrated *in vitro*, the concentrations of JHs or JHAs employed are notably above physiological limits. In addition to the effect of 1 μg (≈65 μM) fenoxycarb on *Bombyx* prothoracic glands discussed above (Dedos and Fugo, 1996), Richard and Gilbert (1991) reported that JHB3 and JHIII both inhibited the secretion of ecdysteroids from *Drosophila* brain–ring gland complexes; however, millimolar concentrations were needed to elicit the effect.

3.2.3.4. PTTH Hemolymph Titer

The periodic increases in ecdysteroid synthesis and hemolymph titer that control molting and molt quality have long been interpreted to indicate that PTTH was itself released periodically into the hemolymph. However, testing this hypothesis has not been simple. Unlike ecdysone and 20E, a sensitive radioimmunoassay for PTTH has not been available until very recently. Instead, the measurement of PTTH hemolymph titers has been done primarily via *in vitro* analysis of prothoracic gland ecdysteroidogenesis using hemolymph extracts.

Bollenbacher and Gilbert (1981) determined the brain and hemolymph titers of PTTH in *Manduca* during the fourth and fifth larval instars, using an *in vitro* bioassay system and discovered little concordance between measured brain- and hemolymph-derived PTTH activities. Brain titers of PTTH rose fairly steadily during this period, punctuated by minor decreases or plateaus. A small dip in brain PTTH was seen immediately after the molt to the fifth larval instar and a larger decrease seen about 1 day prior to the pupal molt. In contrast, hemolymph PTTH activity was low throughout this period with only a few very sharp peaks. In the fourth instar, a single PTTH peak occurred late on day one, also reported later by Bollenbacher *et al.* (1987), with a second small peak spanning the molt to the fifth larval instar. During the fifth larval instar proper, four peaks were noted. Three medium-sized peaks clustered on and about the fourth day, preceding and overlapping the commitment peak of ecdysteroid synthesis. A much larger PTTH hemolymph titer was measured on day six, at the rising edge of the major larval ecdysteroid titer that precedes the metamorphic molt to pupal–adult development and closely anticipating apolysis. The PTTH titer appeared to be rising again, just before pupal ecdysis, but titers were not determined beyond this point.

Later studies of *Manduca* brain PTTH content indicated that PTTH levels in the brain increased considerably during pupal–adult development (O'Brien *et al.*, 1986) but hemolymph titers have yet to be determined at this stage for *Manduca*. These studies suggested that PTTH titers in the brain are not closely correlated with circulating levels, unlike the levels in the corpus allatum (Agui *et al.*, 1980). The PTTH titers described in the Bollenbacher and Gilbert (1981) study, while intriguing, must be considered preliminary for three reasons. First, the bioassay may miss small peaks that are not high enough to activate prothoracic glands *in vitro* but which might act *in vivo* i.e., very low levels of PTTH *in vitro* might be able to stimulate prothoracic gland steroidogenesis with a slower time course than that utilized in the *in vitro* assays. Second, very low levels of PTTH might have biologically significant effects on the prothoracic gland besides stimulating ecdysteroidogenesis. Third, if the so-called small PTTH (see Section 3.2.2.5) is secreted into the hemolymph, then an unknown fraction of the PTTH activity detected in the hemolymph might reflect this incompletely characterized protein rather than "big" PTTH.

Shirai *et al.* (1993) first addressed the topic of PTTH hemolymph titers in *B. mori*. Again, an assay was used in which fifth larval instar hemolymph extracts were tested for PTTH ecdysteroidogenic activity with prothoracic glands *in vitro*. In addition, the secretion of PTTH activity by brain–endocrine complexes was measured with the *in vitro* gland assay. Hemolymph ecdysteroid levels were also determined via radioimmunoassay. The results of this study suggested that five peaks of PTTH activity were present in the hemolymph of *Bombyx* fifth instar larvae. Two of these PTTH peaks occurred in the first half of the fifth instar, clearly before a small ecdysteroid peak on day seven or day eight to nine, depending on the particular *Bombyx* strain-cross utilized (*Shunrei* x *Shougetsu* and *Kinshu* x *Shouwa*, respectively). This small ecdysteroid peak was presumed to be the commitment peak, as seen in *Manduca*. A third PTTH peak occurred the day before the putative commitment peak while the fourth peak encompassed the time span of the commitment peak and just overlapped the beginning of the large premolt ecdysteroid peak. The fifth hemolymph peak detected by Shirai *et al.* (1993) began almost immediately after the finish of the fourth peak and overlapped with approximately the first third of the large ecdysteroid peak. These workers also found four to five peaks of PTTH activity when brain–endocrine complexes were assayed *in vitro*. These peaks anticipated the hemolymph peaks by about one day. These results generally supported the hemolymph peak data and also suggest that, at least in *Bombyx*, isolated brain–endocrine complexes might be released prematurely from negative controls that function *in vivo*. These hemolymph and *in vitro* secretion results are intriguing because they suggest that two to three releases of PTTH may not be ecdysteroidogenic, but might serve additional functions, such as "priming" the prothoracic gland to produce higher levels of ecdysteroids at a later time. This "priming" could represent a trophic effect of PTTH, in which transcription and translation of components of the ecdysteroidogenic synthetic pathway occur.

As was the case for the *Manduca* hemolymph PTTH data (Bollenbacher and Gilbert, 1981), the data obtained by Shirai *et al.* (1993) must be interpreted carefully for several reasons. First, the hemolymph and incubation medium assays measured total PTTH activity, but did not determine if the activity stems from PTTH and/or from other molecules such as small PTTH or bombyxin. Second, the peaks of PTTH activity obtained from both the hemolymph extracts and the brain-endocrine incubations were surprisingly similar in height, i.e., PTTH activity/ml, during the fifth instar, in contrast to the data obtained by Bollenbacher and Gilbert (1981). Third, because the *Bombyx* prothoracic gland is not responsive to PTTH at the beginning of the fifth instar (see Sections 3.2.3.3 and 3.2.5.1), a release of PTTH in the first day or two of the fifth larval instar of *Bombyx* would not be expected to result in a corresponding ecdysteroid peak. However, the lack of an ecdysteroid peak *in vivo* in response to the PTTH activity peak measured around days four to five is surprising, and calls into question the extraction and incubation results.

The development of a highly specific antibody against *Bombyx* PTTH (Mizoguchi *et al.*, 1990) afforded an opportunity to develop a more facile and sensitive method to determine hemolymph PTTH titers. Dai *et al.* (1995) and Mizoguchi *et al.* (2001, 2002) used this antibody in a time-resolved fluoroimmunoassay to study *Bombyx* PTTH hemolymph titers during larval–pupal and pupal–adult development. In addition, Dai *et al.* (1995) utilized this anti-PTTH antibody to assess the PTTH content of brain–retrocerebral complexes, using immunogold electron microscopy.

In the first of these three studies (Dai *et al.*, 1995), the hemolymph PTTH titer was moderately high at the beginning of the fourth instar and reached a minimum about 36 h later (scotophase of day 1, fourth instar (IV_1)). A larger peak ensued, with a slight dip in the photophase of IV_2, with a minimum again just before the molt to the fifth instar. The fifth instar PTTH titer exhibited a small but distinct peak during the first photophase on V_0 with minima 12 h later (V_1) and just at the larval–pupal molt (V_9–P_0). In between the two minima, hemolymph levels climbed fairly steadily to a plateau from V_6 through V_8, at which point a rapid decline to the molt minimum began. The parallel determinations of hemolymph ecdysteroid titer and PTTH antibody reactivity in the corpus allatum (the site of PTTH release; see Section 3.2.3.1) indicated that there was no obvious correlation between PTTH and ecdysteroid hemolymph titers, except during the fourth instar, when both of the PTTH peaks were associated with ecdysteroid peaks. The commitment and large premolt ecdysteroid increases of the fifth larval instar both occurred during the plateau period of high PTTH titer. In contrast, PTTH immunostaining in the corpus allatum was low during the early fifth instar peak (V_1) and during most of the later hemolymph plateau phase of PTTH titer; however, a striking transitory increase in PTTH immunostaining was seen on V_7, just before the rapid decline in hemolymph PTTH titer commenced.

Subsequent to these intriguing observations by Dai *et al.* (1995), it was discovered that the method used to extract the hemolymph for the PTTH fluoroimmunoassay included a hemolymph factor that contributed an unknown amount to the measured PTTH titer (Mizoguchi *et al.*, 2001). Consequently, Mizoguchi *et al.* (2001) repeated the determination of *Bombyx* hemolymph and ecdysteroid titers, using a revised hemolymph treatment protocol. This study also extended through the period of pupal–adult development and included a parallel ecdysteroid titer determination, as well as an analysis of brain PTTH content, using the time-resolved fluoroimmunoassay. Mizoguchi *et al.* (2002) provided a third determination of fifth instar and pupal–adult *Bombyx* hemolymph PTTH and ecdysteroid titers, using the revised fluoroimmunoassay, in conjunction with a study directed at discovering potential rhythmicity in PTTH secretion and the influence of diel light cycles. These two more recent studies contrast in several ways with the data obtained by Dai *et al.* (1995) and Shirai *et al.* (1993). Like Dai *et al.* (1995), Mizoguchi *et al.* (2001) found two hemolymph PTTH peaks in the fourth instar, but only the second one was accompanied by a clear-cut rise in hemolymph ecdysteroids. During the fifth instar, Mizoguchi and colleagues detected three rises and fall of hemolymph PTTH, with the instar ending in a period of rapidly increasing PTTH levels that carried on into pupal–adult development. These studies involved three different crosses of *Bombyx* races and four separate determinations (in the following section, the name of the female race in a cross is given first, and the male second). The earliest of these increases took place on V_4 and rose just slightly above background PTTH levels. Of the two crosses for which complimentary ecdysteroid titers are available, the *Kinshu* x *Showa* (Mizoguchi *et al.*, 2001) exhibited ecdysteroid peaks corresponding to all three PTTH rises (albeit the first ecdysteroid peak is very small). In the *J106* x *Daizo* hybrid (Mizoguchi *et al.*, 2002), only the second and third PTTH peaks are correlated with measurable ecdysteroid peaks, i.e., the small, presumptive commitment and the much larger premolt peaks. In

contradistinction to the associated ecdysteroid peaks, the relative heights of the second and third PTTH increases vary with the hybrid, i.e., the V_5 peak is distinctly higher than the V_7 peak in the *Kinshu* x *Showa* hybrid (Mizoguchi *et al.*, 2001) while in the *J106* x *Daizo* hybrid, the later peak (V_6) is much larger (Mizoguchi *et al.*, 2002). The immunoassay survey of fifth instar brain PTTH by Mizoguchi *et al.* (2001) revealed a period of gradual increase, starting from the first day of the instar and peaking on the fifth and sixth days, followed by a rapid decline to a minimum on the ninth day. PTTH levels then rose slightly on the ninth day and remained static through pupation on the following day.

Pupal–adult PTTH hemolymph titers were analyzed four times by Mizoguchi and colleagues and indicated one or two high peaks of concentration extending over the first half of the stage followed by a period of much lower levels and ending with a variety of levels, low, intermediate, or high, depending on the cross (Mizoguchi *et al*., 2001, 2002). The two parallel ecdysteroid titers exhibited much less variation in temporal patterning. A large, fairly symmetric peak was centered about 48 h after pupal ecdysis and ecdysteroid levels declined rapidly and evenly to very low concentrations by the time of adult ecdysis. The major difference between the two pupal–adult ecdysteroid titers was that of concentration. The *Kinshu* x *Showa* racial hybrids reached levels of more than 7 µg equivalents per ml (Mizoguchi *et al*., 2001) while the *J106* x *Daizo* hybrids peaked at only about 1.5 µg equivalents per ml (Mizoguchi *et al*., 2002).

The five immunologic determinations of *Bombyx* PTTH hemolymph titers, and the three of ecdysteroids, made by Dai *et al*., 1995 and Mizoguchi *et al.* (2001, 2002) paint a fairly similar picture of circulating PTTH levels in *Bombyx*, yet there are several important discrepancies among the results that need to be resolved. First, the small yet distinct early ecdysteroid peak seen in the fourth instar by Dai *et al*. (1995), occurring in consort with the first of the two PTTH rises, was not consistently found in other assays of fourth instar ecdysteroid titers, e.g., possibly seen by Kiguchi and Agui (1981), but not by Gu and Chow (1996) or Mizoguchi *et al*. (2001). Verifying, or disproving, the existence of this ecdysteroid increase is necessary to understand the role(s) of PTTH at this time. Second, the status of hemolymph PTTH levels at the beginning of pupal–adult life is not clear. In two of four assays, a broad peak of hemolymph PTTH was found in early pupal–adult life centered on day 2 (*Kinshu* x *Showa*: Mizoguchi *et al*., 2001; *Showa* x *Kinshu* raised at 25 °C: Mizoguchi *et al*., 2002). In a third profile (*Showa* x *Kinshu* raised at 25 °C: Mizoguchi *et al*., 2002), a peak on the second day after pupal ecdysis was followed by an approximately 2-day plateau of intermediate values, before finishing the last half of pupal–adult life with lower levels but with considerable variation, especially in the 36 h before adult ecdysis. In the fourth instance (*J106* x *Daizo*: Mizoguchi *et al*., 2002), a high, narrow peak of hemolymph PTTH occurred on the first day after ecdysis, followed by a second, broader, peak about 36 h later. A third topic of concern is the level of PTTH circulating at the end of pupal–adult development. Mizoguchi *et al.* (2001) reported an adult ecdysis peak (≈250 pg rPTTH equivalents) that was as high as that seen at the beginning of pupal–adult development, when ecdysteroid levels are also very high. In contrast, PTTH hemolymph titers in the other three pupal–adult studies were only 25% to 50% of the earlier pupal–adult peaks (Mizoguchi *et al*., 2002).

It is not possible currently to assess the reasons for the observed large temporal and concentration variations in PTTH titer. Multiple racial hybrids of *Bombyx* were used and some data came from animals raised on mulberry leaves (Shirai *et al*., 1993), rather than on an artificial diet. The length of the fifth instar ranged from 8 to 12 days while pupal–adult development varied from 8 to 11 days. The possibility that further stage-specific or hybrid-specific factors are influencing the PTTH titer data cannot be ruled out. However, since hybrid-specific differences in ecdysteroid titers were also found, especially in the peak concentrations, and ecdysteroid assays are well standardized, it seems likely that the PTTH titer variations are mainly biologically based. Given this assumption, it is possible to present an average or summary picture of PTTH and ecdysteroid hemolymph titers in *Bombyx* (**Figure 6**). Several conclusions can be drawn from these data. First, it is clear that PTTH increases do not always result in a detectable increase in hemolymph ecdysteroid concentrations and these results suggest that the gland was nearly or absolutely refractory to PTTH stimulation *in vivo* at times when a response was easily detected *in vitro*, e.g., V_6 and V_9 (Okuda *et al*., 1985). This disparity suggests that the prothoracic gland may be subject to negative controls at some stages and that this inhibition of activity is lost when the glands are placed *in vitro*. Another obvious inference stemming from these observations is that PTTH might stimulate nonsteroidogenic events at these times, perhaps in tissues other than, or in addition to, the prothoracic gland.

A second conclusion that originates from the examination of the hemolymph titers of PTTH and

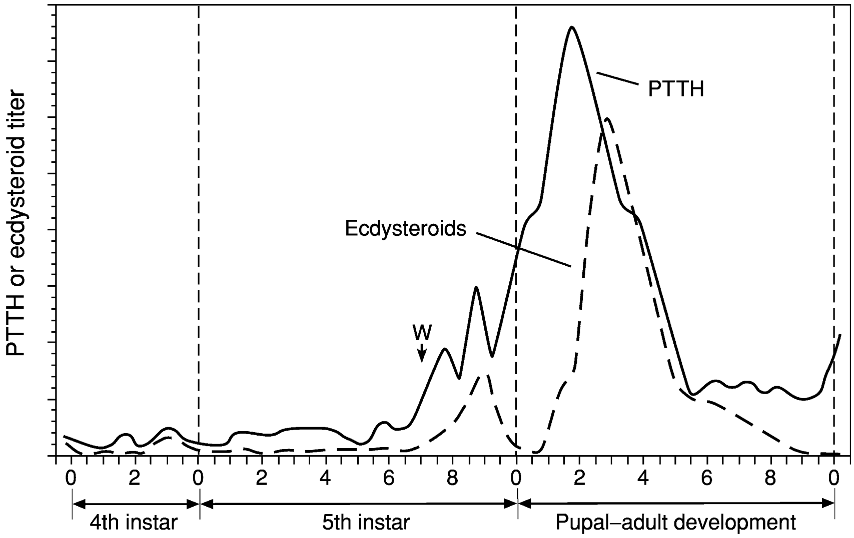

Figure 6 Typical PTTH and ecdysteroid titers in *Bombyx mori* hemolymph. Values are a composite of determinations from Dai *et al.* (1995) and Mizoguchi *et al.* (2001, 2002) and any individual, original profile may vary notably from the constructed profile shown here. W indicates wandering stage.

ecdysteroids is that there might be a negative correlation between peak concentrations of PTTH and peak concentrations of ecdysteroids during pupal–adult development. Thus, during this stage the *Kinshu* x *Showa* hybrid experienced a maximum titer of PTTH ≈270 pg rPTTH equivalents/ml while the associated ecdysteroid peak was ≈7000 ng 20E equivalents/ml (Mizoguchi *et al.*, 2001); in contrast, in the *J106* x *Daizo* hybrids, the temporally comparable peaks were ≈670 pg rPTTH/ml equivalents and ≈1500 ng 20E equivalents/ml, respectively (Mizoguchi *et al.*, 2002).

Third, while peak concentrations of PTTH are not good predictors of pupa–adult ecdysteroid levels, a suggestive two point (!) concordance does occur in the fifth instar. The maximum fifth instar PTTH titer in the *Kinshu* x *Showa* hybrid (≈90 pg rPTTH equivalents/ml) was about half that seen in the *J106* x *Daizo* hybrid, but the peak ecdysteroid level in the *Kinshu* x *Showa* hybrid was more than twice that of the *J106* x *Daizo* cross (≈1600 ng and ≈600 ng 20E equivalents/ml, respectively) (Mizoguchi *et al.*, 2001, 2002).

Fourth, in the *J106* x *Daizo* hybrids, a large temporally narrow peak of PTTH (≈880 pg rPTTH equivalents/ml) occurred immediately after larval–pupal ecdysis, which was not associated with an ecdysteroid peak and which was not seen in the other PTTH titer profiles (Mizoguchi *et al.*, 2001, 2002). The failure to see a corresponding ecdysteroid peak may not be surprising, given evidence from *in vitro* studies indicating that the prothoracic gland might be refractory to PTTH stimulation during the period of larval–pupal ecdysis (Okuda *et al.*, 1985). What this peak does suggest is that our understanding of factors involved in PTTH release and metabolism is rudimentary. One missing factor in this equation may well be juvenile hormone, the values of which were not addressed in these studies, but other hormones and factors are also likely involved.

Finally, the variation found in PTTH and ecdysteroid titers and in developmental rates, originating from methodologically similar studies (Dai *et al.*, 1995; Mizoguchi *et al.*, 2001, 2002), clearly indicate that more data are desirable from *Bombyx* and from other insects such as *Manduca*. Only then will we obtain a reliable picture of how this important piece of the insect endocrinological system functions. The open questions are many. For instance, how much does the magnitude of a PTTH peak matter? Do very high levels have unique biological effects on the prothoracic glands, or do they simply delay processes that depend on low PTTH levels for their expression or regulation? What are the targets and consequences of the orphan peaks, i.e., PTTH increases that do not elicit ecdysteroidogenesis? What is the role of PTTH in late pupal–adult development and during adult life, when prothoracic glands are generally absent due to programmed cell death?

3.2.3.5. PTTH: Rhythms and Cycles

The above discussion of PTTH hemolymph titers has concentrated on the issues of the timing and magnitude of stage-specific peaks. However, a number of studies have yielded data that showed that some PTTH peaks are "gated," that is, occur only within a narrow window within a 24 h light–dark

cycle. Some evidence also suggests that a circadian variation in PTTH titer is overlaid upon the broader sweeps of changing PTTH levels. Steel and Vafapoulou (see **Chapter 3.11**) cover the subject of circadian rhythms in detail (see also Giebultowicz, 2000; Steel and Vafapoulou, 2002; **Chapter 4.11**); only a brief treatment is given here.

Head critical period (HCP) is a term used to refer to a developmental period before which the presence of the head (brain) is necessary for later events to transpire. In the case of ecdysteroid-triggered events, the HCP has generally been used as a marker for PTTH release. Studies of the HCP for molting provided the first data indicating that an endocrine-dependent event in insect development involved circadian cycles (Truman, 1972). This work revealed that larval molting and the HCP for molt initiation in *Manduca* and *A. pernyi* were temporally gated. Since this HCP and ecdysis are ultimately controlled by PTTH, via ecdysteroid levels, these observations implicated the involvement of a circadian clock in PTTH release. Further work in *Manduca* (Truman and Riddiford, 1974) demonstrated that the PTTH release responsible for inducing wandering in the last larval instar, as revealed through HCP timing, was also temporally gated, again indicating the participation of a circadian clock. In *Samia cynthia ricini*, the HCP for gut purging was also gated (Fujishita and Ishizaki, 1982) but not every HCP is necessarily under the control of a photoperiodically controlled circadian clock. For instance in *Samia*, in contrast to the HCP for gut purging, the HCP for pupal ecdysis, which follows wandering by 2 days, was unaffected by shifts in the photoperiod conditions and appeared to be a constant (≈96 h) (Fujishita and Ishizaki, 1982). Light-entrained circadian rhythms in endocrine-dependent events are not confined to the Lepidoptera, of course, and have been studied in a number of other taxa, such as the Diptera. For instance, in *S. bullata* (Roberts, 1984) and *S. argyrostoma* (Richard *et al*., 1987) larval wandering is under strong photoperiodic control. A similar result was seen with *D. melanogaster*, if they were raised under long day (16 : 8) and low-density conditions (Roberts *et al*., 1987).

More recent work on *Rhodnius prolixus* and the recent surveys of PTTH hemolymph titers have suggested that there might be diel variations in titer, and presumably PTTH release, which are superimposed upon the larger peaks and plateaus of circulating PTTH levels. In *Bombyx*, data from the fifth larval instar and from pupal–adult development (Sakurai *et al*., 1998; Mizoguchi *et al*., 2001) suggested that there may be such a daily cycling of PTTH hemolymph levels; a similar suggestion was seen in the *in vitro* secretory activity of prothoracic glands from the last 4 days of the fifth instar (Sakurai *et al*., 1998). To examine this possibility more directly, Mizoguchi *et al*. (2001) phase shifted two groups of initially synchronous *Bombyx* larvae on the first day of the fifth instar, such that their light–dark periods were displaced by 12 h from one another. After 5 days, both groups exhibited a peak in PTTH hemolymph titer that began at the scotophase-photophase transition and peaked during the photophase, supporting the hypothesis that light–dark cycles influence some periods of PTTH release. However, the careful temporal analysis of PTTH titers afforded by this study did not indicate that every apparent PTTH peak was so influenced. In both phase-shifted populations, a second PTTH peak was observed that varied between the two groups in time of appearance (30 h versus 48 h), with one of the following peaks occurring during the scotophase and the other during the photophase. Thus, this study did not support the notion of small daily PTTH peaks.

The strongest and most direct evidence for circadian rhythms in PTTH levels and consequent ecdysteroid hemolymph levels comes from studies of the bug *R. prolixus* and the cockroach *P. americana*. In *Rhodnius*, during the last two-thirds of the final larval instar, PTTH synthesis and release appears to be controlled by a circadian clock, with peaks occurring during the scotophase (Vafopoulou and Steel, 1996; see **Chapter 3.11**). The implications of this rhythmicity for ecdysteroid synthesis are not straightforward, as studies *in vitro* revealed that the *Rhodnius* prothoracic gland exhibited circadian cycling of ecdysteroid synthesis in the absence of PTTH, although with a phase shift to peaks during the photophase (Pelc and Steel, 1997). Steroid synthesis in animals that had been either decapitated or paralyzed with tetrodotoxin, to ablate PTTH release, exhibited a rhythmicity similar to that seen *in vitro*, and the composite results indicate that PTTH is an important entraining factor for the circadian clock regulating ecdysteroid synthesis. The endogenous clock of the prothoracic gland is light entrained, specifically by a “lights-off” cue (Vafopoulou and Steel 1998, 2001). A “lights-off” cue also functions in controlling PTTH release, as shown in experiments where PTTH release was abolished under continuous light but promptly restored after transfer to dark conditions (Vafopoulou and Steel 1998, 2001). Further complexity in the control of ecdysteroidogenesis by PTTH in *Rhodnius* was indicated by the discovery that prothoracic glands also express a daily rhythm in PTTH responsiveness, i.e., PTTH receptivity is gated (Vafopoulou and Steel, 1999).

In the cockroach *P. americana*, isolated prothoracic glands did not exhibit a circadian cycling of ecdysteroid synthesis *in vitro* when they had been extirpated from stages that exhibit daily cycles of ecdysteroids in the hemolymph, i.e., the last several days of the last larval instar (Richter, 2001). However, if the *Periplaneta* glands were co-cultured with brains taken from such late instar animals, then a diel rhythm in ecdysteroidogenesis resulted, with a peak in the scotophase matching the *in vivo* hemolymph pattern (Richter, 2001). As discussed earlier (Section 3.2.3.2), melatonin dramatically increased the secretion of PTTH from brains *in vitro* during a scotophase, with lesser increases seen during a photophase (Richter, 2001). These data suggested that PTTH release might be, at least partially and at only some stages, regulated by melatoninergic neurons. This PTTH cycling would result in a circadian variation in ecdysteroid synthesis and hemolymph titer. Nonetheless, further support for this hypothesis has yet to be marshaled. In particular, a demonstration of PTTH cycling *in vivo*, preferably in the hemolymph titer, would be supportive because factors other than PTTH might be driving prothoracic gland cycles, e.g., input from nerves that synapse with the prothoracic gland in *Periplaneta* (Richter, 1985).

The existence of light-dependent cyclic or rhythmic behavior by an organism or a tissue or single cell indicates the presence of a light-sensing system as well as an actual molecular-based clock. In cases where isolated brains or prothoracic glands cyclically release hormones under *in vitro* conditions, the sensing apparatus and clock(s) must reside within some or all of the cells under study. A light-sensing system implies the presence of a photoreceptive protein or a photopigment coupled to a transduction system. In the instance of PTTH and ecdysteroid cycling observed *in vitro* in *Rhodnius* tissues, such a sensing system must be extraretinal. In *Drosophila*, one such protein is known, cryptochrome, which absorbs in the blue, and functions as an extraocular photoreceptor in the lateral neurons of the brain (see Stanewsky, 2002, 2003). In a series of clever experiments involving gland transplantation, selective illumination of larval regions and phase-shifting of gut purge, Mizoguchi and Ishizaki (1982) showed that the prothoracic gland of *Samia cynthia* possesses both a photoreceptor and an endogenous clock; it seems likely that a cryptochrome is the photoreceptor in this system.

The actual cellular molecular clock has been studied extensively in *Drosophila* where the central oscillator is formed by a complex feedback loop involving the transcription, translation, and phosphorylation of at least seven genes: *period*, *timeless*, *clock*, *cycle*, *doubletime, vrille*, and *shaggy* (Stanewsky, 2002, 2003) (see **Chapter 4.11**), and possibly *cryptochrome*, which appears to function as part of the "central oscillator" in some peripheral tissues (Krishnan *et al*., 2001). The presence of cryptochrome in the prothoracic glands has not been determined but the *period* and *timeless* proteins have been immunologically detected in the *Rhodnius* gland (Terry and Steel, cited in Steel and Vafapoulou, 2002) and in the prothoracic gland portion of the *Drosophila* ring gland (Myers *et al*., 2003). At least some of the proteins involved in the *Drosophila* central oscillator shuttle between the nucleus and the cytoplasm, and cycles of abundance of both protein and mRNA are characteristic. For a more thorough understanding of these processes, (see **Chapters 3.12**, **4.11**, and Saunders (2002)).

The expression of the *period* protein in insect brains has been the subject of several immunohistochemical studies in insects other than *Drosophila*. In the *Rhodnius* brain, a small group of neurons adjacent to the prothoracicotropes (one per hemisphere) were immunopositive for the *period* and *timeless* proteins (Terry and Steel, cited in Steel and Vafapoulou, 2002). Sauman and Reppert (1996a) found that two pairs of dorsolateral neurons, per hemisphere, were immunopositive for *period* in the brain of the moth *A. pernyi*, and that the cell bodies were in contact with the two pairs of dorsolateral neurosecretory cells that were immunopositive for PTTH. Interestingly, the *period* positive cells sent their axons to the corpus cardiacum whereas PTTH-producing neurons course contralaterally to terminate in the corpus allatum. Thus, if the PTTH- and period-producing cells communicate with one another it is likely to be at the level of the cell bodies, perhaps via tight junctions, or in the corpus cardiacum, where the "*period* cells" could transmit information to boutons on the axons of the "PTTH neurons." Interestingly, only cytoplasmic and axonal *period* staining was observed in the *Antheraea* brain (Sauman and Reppert, 1996b); the expected nuclear presence was not seen, although temporal cycling of protein and mRNA was observed. Závodská *et al*. (2003) surveyed the cephalic nervous systems of 14 species of insects, representing six orders, using immunohistochemical methods and antibodies against *period*, PTTH, and pigment-dispersing hormone (PDH, also known as pigment-dispersing factor), as well as eclosion hormone. PDH-expressing neurons are also important in circadian processes, although their role appears to be information transfer between cells rather than direct participation in the intracellular molecular

clock oscillator (Stengl and Homberg, 1994; Helfrich-Förster *et al*., 2000). A detailed recapitulation of the data obtained in this study is beyond the purposes of this review but a few results are worth noting. First, *period* was widely distributed, with most species showing antibody reactivity in cells of the optic lobe, pars intercerebralis, and the dorsolateral protocerebrum. Second, *period* staining was limited to the cytoplasm. Third, PDH exhibited the most consistent immunoreactivity, being found in the optic lobes of all 14 species. Finally, none of the cells immunopositive for any one of the four antigens was also immunopositive for any of the other three antigens. Thus, to the extent that these four proteins play a role in circadian cycles, the data suggest that such cycles are controlled, at least within the brain, by a nexus of cells rather than a discrete nucleus.

Obviously, we are currently still in the early stages of understanding the molecular and physiological mechanisms that control cyclical PTTH release. The studies reviewed here, as well as others, suggest that there are several ways in which the PTTH-prothoracic gland axis may entrain rhythms in steroid levels. It is not yet possible to say whether these varied circadian systems sort out along taxonomic, or ecological, or other grounds. Furthermore, we know essentially nothing about the removal or degradation of PTTH from the insect circulation. Changes in the PTTH hemolymph titer must be regulated not only by synthesis and release, but also by processes of sequestration and/or proteolysis. Whether or not there are PTTH-specific uptake, elimination, or proteolytic pathways is totally unknown, but it seems unlikely that the prothoracic gland will be the only tissue found to be involved in these processes. More work on these problems is clearly needed, involving not only “modern” molecular genetics, but “old-fashioned” biochemistry and physiology as well.

3.2.3.6. PTTH and Diapause

All organisms face variations in their environment, and even in the most equable habitats, confront periods during which they must alter their behavior and/or their physiology to cope with stressful conditions. When such nonfavorable circumstances are neither too severe nor prolonged, behavioral changes or simple homeostatic mechanisms are generally evoked. When these changes are harsher, such as nonseasonal drought or the protracted cold of temperate zone winters, then more sweeping actions are taken. At the physiological level, insects and many other arthropods deal with unpredictable environmental challenges by becoming quiescent. Simple quiescence involves rapid and temporary cessation of activity and the animal quickly resumes its activity when the hostile conditions cease. When the adverse conditions are relatively predictable, e.g., winter or seasonal drought, then the solution of most insects is to enter diapause (see **Chapter 3.12**). Diapause is a type of dormancy that involves perception of one or more predictable environmental cues that anticipate and predict regularly occurring, unfavorable conditions. Animals in diapause express physiological mechanisms that greatly increase their ability to resist environmental challenges that range from desiccation to freeze-damage resistance. The cues that trigger diapause are not necessarily the conditions that the behavior has evolved to escape or moderate, e.g., organisms that enter a winter diapause state may be stimulated to do so by shorter day length rather than by falling temperatures. Diapause involves a genetically determined response that is controlled by the neuroendocrine system. Diapause is obligate or facultative, and undergone by embryos, larvae, pupae, or adults, depending on the species. For broader views of diapause than presented here, see Tauber *et al.* (1986); Danks (1987); and **Chapter 3.12**.

The PTTH-ecdysteroid axis has been implicated in the control of both larval and pupal diapause. *Manduca* larvae molt into diapausing pupae after being raised under a short-day (e.g., 12 h) photoperiod. Bowen *et al.* (1984a) found that such animals exhibit a much reduced hemolymph ecdysteroid titer relative to developing pupae. Low ecdysteroid titers have been documented in other Lepidoptera and other taxa that undergo a pupal diapause, e.g., the moths *H. cecropia* (McDaniel, 1979) and *Heliothis virescens* (Loeb, 1982), and the flesh flies *Sarcophaga crassipalpis* (Walker and Denlinger, 1980) and *S. argyrostoma* (Richard *et al*., 1987). Bowen *et al.* (1984a) showed that two factors resulted in the low levels of circulating ecdysteroids during diapause. First, diapause prothoracic glands were found to be refractory to PTTH stimulation when tested *in vitro*. Smith *et al*. (1986a) found that the refractory state in diapausing pupae could be simulated in nondiapausing pupae by removal of the brain, indicating that the presence of a brain-derived factor is necessary to retain prothoracic gland responsiveness. PTTH is, of course, a prime candidate to function in such a trophic context (see Section 3.2.3.6) but a role for other hormones cannot be ruled out. Smith *et al.* (1986a) also determined that the refractory “blockade” in the *Manduca* prothoracic gland is downstream from the PTTH receptor, Ca^{2+}-influx, and cAMP generation (see Section 3.2.3.4 for a discussion of the PTTH transduction cascade). The use of a calcium

ionophore and a cell-permeable cAMP analog both failed to stimulate ecdysteroid synthesis in the diapause glands, although these agents are as effective as PTTH when applied to nondiapause glands. However, PTTH stimulated cAMP accumulation within diapause glands, in fact to levels higher than seen under nondiapause conditions. This observation indicates that there is not also a block upstream from cAMP generation, such as a downregulation in the numbers of PTTH receptors or adenylate cyclase molecules. Similar data, indicating a signal transduction lesion downstream from cAMP generation, were obtained by Richard and Saunders (1987), studying diapause in the flesh fly *Calliphora vicina*. Basal protein kinase A activity in *Manduca* day 10 diapause glands was ≈20% lower than that seen in nondiapause day 0 pupal glands, but both pupal and diapause protein kinase activity approximately doubled in response to dibutyryl cAMP (Smith *et al*., 1987a). Thus, lowered protein kinase A activity is likely contributory to the refractory nature of diapause prothoracic glands but other factors are undoubtedly involved.

Bowen *et al*. (1984a) suggest that the second reason for low ecdysteroid levels in diapause pupae is the absence of PTTH. These workers found that, in *Manduca*, during the first 20 days of diapause, the content of PTTH in the brain or in the brain–retrocerebral complex did not differ significantly from that in nondiapausing, developing pupae. Bowen and colleagues construed these data to indicate that PTTH release was greatly curtailed during diapause but the interpretation of this result is, unfortunately, not straightforward since it is possible that PTTH catabolism in the hemolymph was increased; note that the hemolymph PTTH titer was not measured in this case. In fact, Bowen *et al*. (1986) studied the release of PTTH *in vitro* from *Manduca* brain-retrocerebral complexes and found no difference between complexes from nondiapause and diapause pupae. PTTH release *in vitro* from diapause complexes could have been an artifact stemming from dissection or incubation conditions, or might indicate a release from an *in vivo* inhibitory factor that is lost or inhibited itself under the *in vitro* regimen. If PTTH release is indeed inhibited *in vivo* in diapausing pupae, then data from nematodes may provide a clue to one step in its control, i.e., Tissenbaum *et al*. (2000) found that the diapause-like dauer state of *C. elegans* and *Ancylostoma caninum* was broken rapidly by muscarinic agents. Furthermore, dauer recovery was inhibited by atropine, a muscarinic antagonist. This finding is of note because both Agui (1989) and Shirai *et al*. (1994) showed that cholinergic agents caused the release *in vitro* of PTTH from lepidopteran larval complexes. A dopaminergic pathway may also play a role in diapause, but in contrast to the muscarinic system, dopamine may be involved in inducing or maintaining diapause (see **Chapter 3.12**). Some insects that undergo pupal diapause may exhibit a more complex control of the PTTH-prothoracic gland axis. Williams (1967) was not able to detect PTTH activity in brains from diapausing *H. cecropia* or *Samia cynthia*, in contrast to *A. pernyi*. These data suggest that the stronger diapause in *Hyalophora* and *Samia* is characterized by a period of very low PTTH levels in the brain; whether or not the prothoracic glands are refractory to stimulation at these times was not investigated.

Recently, Xu and Denlinger (2003) studied the levels of PTTH mRNA in brains of *H. virescens* nondiapause and prediapause larvae, and nondiapause and diapause pupae. They found that mRNA levels in nondiapause animals remained relatively constant through the fifth instar until about day 10 of pupal–adult development. However, in prediapause larvae, PTTH mRNA levels dropped at the onset of wandering and, in diapause pupae, the mRNA levels remained low through at least the first 10 days of diapause. These results may reveal the mechanism behind the low PTTH levels seen in diapausing *H. cecropia* or *S. cynthia* pupae, as reported by Williams (1967).

Data from *Manduca* indicate that the PTTH-producing neurosecretory cells undergo morphological and electrophysiological changes during diapause. Hartfelder *et al*. (1994) found no significant differences in cellular ultrastructure between developing pupae and early diapause pupae. However, as diapause progressed, a number of cellular structures exhibited changes, e.g., neurosecretory granules were concentrated into large clusters that were separated by well-organized rough endoplasmic reticulum, notably fewer Golgi complexes were seen, and interdigitations with glial cells were decreased. When diapause was terminated by exposure to warm conditions (26 °C versus 4 °C), the PTTH cells reverted to prediapause morphology within 3 days. Progressive differences in electrophysiological properties between diapausing and developing pupae were found by Tomioka *et al*. (1995), who noted that the diapausing PTTH cells gradually became less excitable. This relative refractoriness was caused by a rise in the threshold value for action potential generation and a decrease in the input resistance.

The endocrine control of larval diapause appears to be more varied than pupal diapause. In

the European corn borer, *O. nubilalis*, larval diapause is similar to *Manduca*. Hemolymph ecdysteroid titers are significantly lower in prediapause larvae than in developing animals (Bean and Beck, 1983) and brain PTTH levels were the same in diapause and nondiapause animals, for at least the first 4 weeks of diapause (Gelman *et al*., 1992). Gelman and colleagues also found that diapause prothoracic glands were highly refractory to PTTH stimulation, as seen in *Manduca*. It must be pointed out that although these results are very reminiscent of the *Manduca* findings, the only PTTH activity detected in diapause brains of *Ostrinia* had an apparent MW of ≤ 5 kDa (Gelman *et al*., 1992). In contrast, the south-western corn borer, *Diatraea grandiosella*, which undergoes up to three stationary molts during diapause, appears to maintain an active PTTH-prothoracic gland axis during larval diapause; its diapause is controlled by high JH levels (Chippendale and Yin, 1973; Yin and Chippendale, 1973; Chippendale, 1984) (see **Chapter 3.12**). High JH levels are also responsible for provoking and sustaining larval diapause in the rice-stem borer, *Chilo suppressalis* (Yagi and Fukaya, 1974); the exact state of the PTTH-prothoracic gland axis during larval life in this species appears to be unknown.

In larval and pupal diapause that are characterized by low ecdysteroid levels, the available evidence suggests that the relative quiescence of the prothoracic glands reflects decreased PTTH release and stimulation. This in turn suggests that the photoperiodic clock involved in the control of PTTH in short-day versus long-day developmental programs might reside in the brain, where PTTH is synthesized. This hypothesis was elegantly addressed with experiments that involved *in vitro* reprogramming of larval brains with altered light cycles (Bowen *et al*., 1984b). In brief, brains from short-day larvae were exposed to a long-day light treatment for 3 days *in vitro* and then implanted into short-day larvae destined to enter diapause. Approximately half of these host larvae did not enter diapause, i.e., the implanted brains reversed the diapause program. If the transplanted brains received a short-day light treatment *in vitro* prior to implantation, then very few host larvae failed to enter diapause. The composite data showed that the three main regulators of pupal diapause in *Manduca* reside in the brain: photoreceptor, clock, and hormonal effector. The main hormonal actor in this developmental program is clearly PTTH, but other factors might well be involved (see **Chapters 3.11** and **3.12**). For instance, brains in animals destined to diapause might secrete an ecdysiostatic factor to downregulate prothoracic gland activity in addition to curtailing PTTH release after pupal ecdysis (see Section 3.2.5.2).

The literature on diapause in insects is very large (see **Chapter 3.12**) and only a very small fraction of it has been reviewed here. Given the long evolutionary history of insects, it is likely that there are additional variations in the ways in which environmental cues, receptors, PTTH, and the prothoracic glands interact to induce or modulate diapause.

3.2.4. PTTH: Signal Transduction in the Prothoracic Gland

Hormones are intercellular messengers that alter the behavior of the target cells. PTTH has only one known target tissue, the prothoracic gland (the possibility that PTTH affects other tissues is discussed in Section 3.2.3.6), and the ultimate response of the gland to PTTH is to increase ecdysteroid production. This section considers the transduction changes in the prothoracic gland elicited by PTTH, and how these changes connect to increased ecdysteroidogenesis. The reader is referred to **Chapter 3.3** for a discussion of the actual synthetic pathway leading from sterols to ecdysteroids. The present discussion has been organized to present the biochemical events of PTTH signal transduction in a sequential or temporal order, so far as we currently understand them. Of course, as events proceed from the initial contact of PTTH with the prothoracic gland and the PTTH receptor, it becomes increasingly likely that multiple PTTH-dependent phenomena occur simultaneously; indeed, it would be a mistake to conceive of any signal transduction cascade as a linear, vectorial process, rather than a complex nexus of interconnected pathways. By using an "outside-in" cellular approach to this topic, a broad chronological view will not be presented, but within each of the subtopics, some history of the field will be afforded. An overview of the PTTH signal transduction pathway, as discussed below, is provided in **Figure 7**.

3.2.4.1. The PTTH Receptor and Associated Proteins

A PTTH receptor has not yet been purified or cloned, so the present section is speculation based on data primarily from *Manduca* and *Bombyx*, and using information gleaned from other characterized peptide receptor systems. PTTH is a circulating, hydrophilic protein and can be expected to bind to a receptor that exposes an extracellular binding site and traverses the cell membrane. PTTH binding to

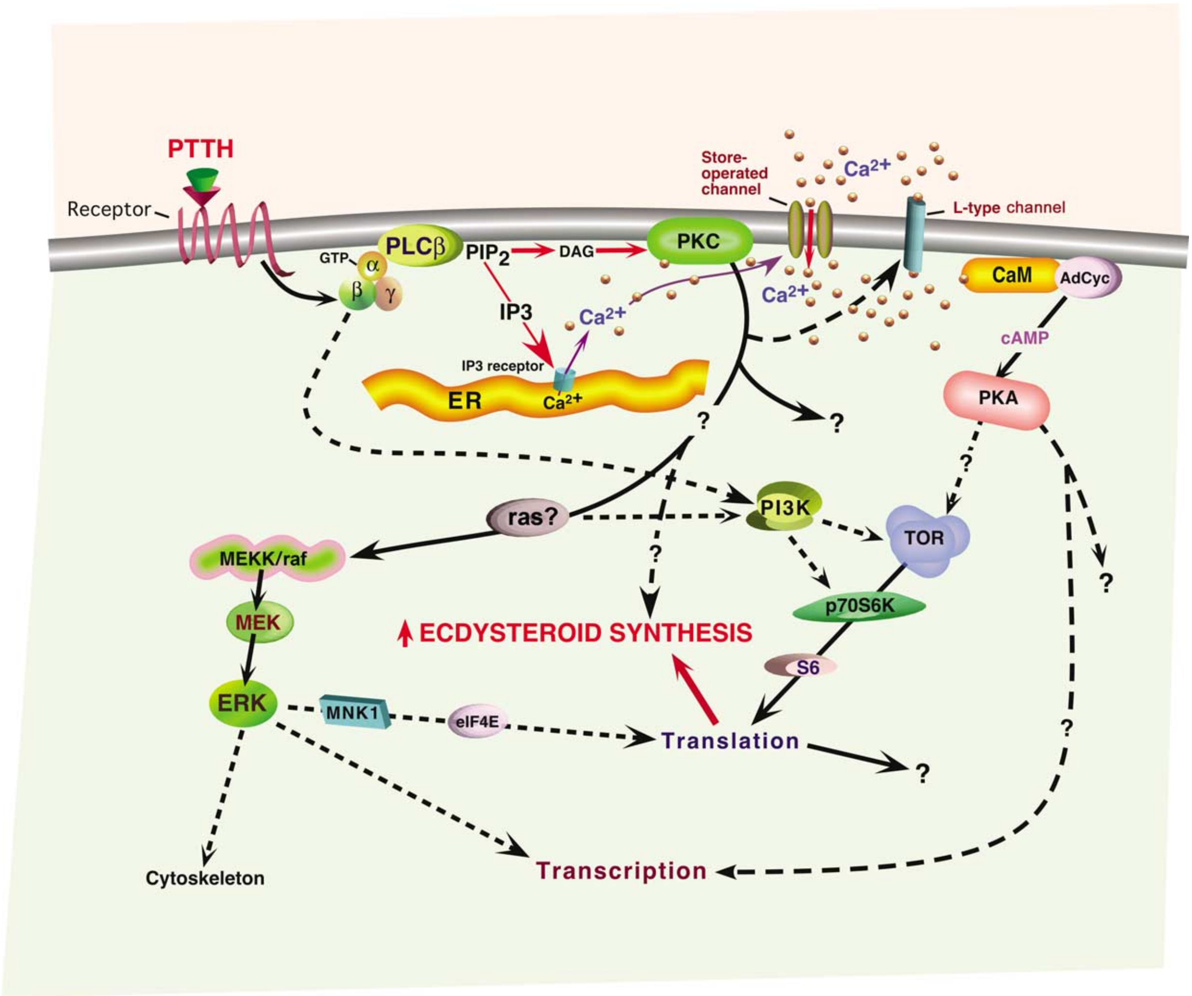

Figure 7 The PTTH signal transduction cascade in prothoracic gland cells. Solid lines indicate demonstrated or highly likely interactions while dashed lines indicate hypothetical relationships. Abbreviations: PTTH, prothoracicotropic hormone; PLCβ, phospholipase C β; PIP_2, phosphatidylinositol-4,5-bisphosphate; DAG, diacylglycerol; IP_3, inositol triphosphate; GDP, guanosine diphosphate; GTP, guanosine triphosphate; cAMP, cyclic adenosine monophosphate; CaM, calmodulin; AdCyc, adenylate cyclase; ER, endoplasmic reticulum; PKA, protein kinase A; PI3K, phosphoinositide 3OH-dependent kinase; TOR, target of rapamycin; MEKK, MEK kinase; MEK, MAPK/ERK kinase; ERK, extracellular signal-regulated kinase; S6, ribosomal protein S6; p70S6K, 70-kDa S6 kinase; MNK 1, MAP kinase-interacting kinase 1; ras, a small GTP binding protein; raf, raf serine-threonine kinase; and eIF-4E, eukaryotic translation initiation factor 4E.

the receptor is likely a high affinity interaction, with a K_D in the very low nanomolar or high picomolar range. Such an affinity is typical for peptide receptors and is also suggested by the findings that *Manduca* recombinant PTTH at ≈0.300 nM was sufficient to maximally stimulate ecdysteroidogenesis *in vitro* (Gilbert *et al*., 2000). More limited data from *Bombyx* also indicated that a similarly low concentration (≈1.7 nM) of *Bombyx* recombinant PTTH was sufficient to elicit maximal ecdysteroidogenesis *in vitro* (Dedos *et al*., 1999). Eukaryotic membrane receptors fall into several broad classes and it seem most likely that the PTTH receptor belongs to the G-protein coupled receptor (GPCR) superfamily (for an insect-oriented review, see **Chapter 5.5**). This is a very large group of proteins that bind a diverse array of ligands. GPCRs span the membrane seven times, with connecting intracellular and extracellular loops. The ligand-binding site is located in an extracellular region. Intracellular areas of the GPCRs interact with the heterotrimeric G-proteins, which are the first-level effectors of an activated ligand-bound GPCR. The direct and indirect targets of activated G-proteins, released from a GPCR by ligand-occupancy, are many and include adenylyl cyclase (see Pieroni *et al*., 1993), which generates the second messenger cAMP from ATP. PTTH evokes a rapid generation of cAMP in

prothoracic gland cells (see Section 3.2.4.2) and, currently, it appears that the generation of cAMP in response to an extracellular ligand almost always involves a GPCR. GPCRs range from <400 to ≈1000 amino acids in size, are glycosylated, and occur as hetero- or homooligomers (see Gazi *et al*., 2002).

The heterotrimeric G-proteins (α, β, and γ) that characterize GPCRs are a genetically diverse group. In both mammals and insects, a considerable number of Gα, Gβ, and Gγ proteins are expressed and the specific subunits that associate with a given GPCR determine to a large degree the particular signaling pathways activated by that GPCR. For example, $G\alpha_s$ stimulates adenylate cyclase activity and $G\alpha_q$ activates phospholipase C (see Offermanns, 2003) and some Gβγ subunits can also activate phospholipase C (see Boyer *et al*., 1994; Morris and Scarlata, 1997). The presence of G proteins in *Manduca* prothoracic glands was investigated by Meller and Gilbert (1990) using Western blotting and cross-linking techniques with antibodies against mammalian Gα and Gβ proteins. Their results suggested that several Gα and Gβ proteins are expressed in the glands and that they likely occur, as expected, in multimeric complexes. Meller and Gilbert also used an antibody against $G\alpha_S$ in an immunoprecipitation experiment and found that $G\alpha_S$ in the prothoracic gland was associated with adenylate cyclase. This observation is congruent with the proposal that the PTTH receptor is a GPCR but, obviously, the association of the G protein–cyclase complex with another receptor cannot be ruled out. Girgenrath and Smith (1996) studied the effects of pertussis and cholera toxins on PTTH-stimulated ecdysteroid synthesis in *Manduca* prothoracic glands; these toxins inhibit and stimulate, respectively, the activity of some G proteins. Pertussis toxin had no effect on PTTH-stimulated ecdysteroid synthesis, but cholera toxin stimulated ecdysteroid synthesis. Cholera toxin also stimulated ecdysteroid synthesis by *Bombyx* prothoracic glands (Dedos and Fugo, 1999c). These observations suggested that PTTH acts through a $G\alpha_s$ protein. Pertussis toxin also had no effect on mastoparan- or PTTH-stimulated Ca^{2+} influx in *Manduca* prothoracic glands (Birkenbeil, 2000).

Several additional pharmacological agents that are known to have effects on GPCR–G protein interactions have been used to investigate further the role of G proteins in PTTH signaling. Mastoparan, a wasp venom that activates G proteins among its other effects caused a dose-dependent increase in intracellular Ca^{2+} (Birkenbeil, 1999), but a dose-dependent decrease in ecdysteroid production in *Manduca* prothoracic gland cells (Birkenbeil, 2000). Injection of GDP-β-S, an inhibitor of G protein activation, failed to block PTTH-stimulated Ca^{2+} influx; PTTH-stimulated ecdysteroid synthesis was not measured in this context (Birkenbeil, 2000). In contrast, the compound suramin, which uncouples G proteins from GPCRs among other effects, blocked PTTH-stimulated Ca^{2+}influx in *Bombyx* (Birkenbeil, 2000) while in *Manduca*, suramin inhibited PTTH-stimulated ecdysteroid synthesis (Rybczynski and Gilbert, unpublished data). The collective data from these laboratories suggest that the PTTH is coupled to a G protein and that the prothoracic gland expresses a number of Gα proteins, at least one of which is not coupled to the PTTH receptor. The supposition that prothoracic glands express multiple Gα proteins is in accord with the immunoblotting results of Meller and Gilbert (1990) discussed above and it is possible that PTTH receptors couple to more than one type of G protein.

If the PTTH receptor is a GPCR, then a number of proteins, besides the G proteins, likely associate with the receptor, at least at some times. These include proteins that are involved in receptor desensitization, such as a PTTH receptor-specific kinase, second messenger kinases (like cAMP-dependent protein kinase A), regulators of G protein signaling (RGS proteins) and arrestins (which bind phosphorylated receptors). If the PTTH receptor undergoes agonist-induced internalization, then proteins comprising the relevant endocytic pathway, e.g., clathrin, and subsequent degradative or recycling pathways would be periodically associated with the receptor. Desensitization and receptor cycling are complex topics. Another fascinating group of GPCR-interacting proteins is the RAMP (receptor activity modifying proteins), a family of proteins identified in vertebrates (see Morfis *et al*., 2003). RAMPs contain a single transmembrane domain, heterodimerize with GPCRs, and the specific RAMP in the heterodimer can determine the ligand recognized by the receptor complex. Developmentally specific RAMP associations with a PTTH receptor could explain the puzzling decrease in the ability of small PTTH to stimulate *Manduca* pupal glands (see Section 3.2.2.5). Naturally, such an interaction is purely hypothetical at this point, given that a search of the *Drosophila* genome database did not reveal any obvious RAMP homologs (unpublished data).

Further speculation on the PTTH receptor and associated proteins is premature at this time and the field will only progress once an authentic receptor has been isolated and characterized. The

field of membrane receptors is a vast one and for detailed discussions on GPCRs, the interested reader should see reviews by Böhm *et al.* (1997); Vázquez-Prado *et al.* (2003), and **Chapter 5.5**, among many others.

3.2.4.2. Second Messengers: Ca^{2+}, cAMP, and Inositols

The activation of GPCRs results in a transient increase of second messenger molecules within the cell. These small molecules carry and expand the intracellular "reach" of the receptor ligand, the first messenger, by binding to numerous target molecules. Ca^{2+} is perhaps the most common of second messengers. The concentration of free Ca^{2+} in the cytoplasm is well buffered and transient increases alter the behavior of Ca^{2+}-binding proteins. Increases in Ca^{2+} can originate from the extracellular environment as well as from internal stores, such as those in the endoplasmic reticulum (see Berridge *et al.*, 2000). Smith *et al.* (1985) found that extracellular Ca^{2+} was crucial for PTTH-stimulated ecdysteroid synthesis in *Manduca* prothoracic glands and that Ca^{2+} influx was a very early event in the PTTH transduction pathway, i.e., cAMP analogs that stimulate ecdysteroid synthesis are still effective in the absence of extracellular Ca^{2+}, indicating that Ca^{2+} influx precedes cAMP synthesis (see below). Smith *et al.* (1985) reported also that basal ecdysteroidogenesis was insensitive to the presence or absence of external Ca^{2+}, as also later noted by Gu *et al.* (1998) for *Bombyx* prothoracic glands, and Henrich (1995) for *Drosophila* ring glands. In contrast, Meller *et al.* (1990) found that basal ecdysteroidogenesis in *Manduca* glands was decreased, although not absent, in Ca^{2+}-free medium, and varied with stage of development; Dedos and Fugo (1999b) uncovered a similar, developmentally specific Ca^{2+}-dependency for basal ecdysteroid synthesis in *Bombyx* glands. Thus, whether or not basal ecdysteroidogenesis is responsive to short-term changes in external Ca^{2+} is not certain; differences in experimental technique might well determine a gland's sensitivity in this regard.

External Ca^{2+} has been shown to be important for PTTH-stimulated ecdysteroidogenesis in at least two other insect species. PTTH-stimulated ecdysteroid synthesis by *Bombyx* prothoracic glands also required the presence of Ca^{2+} in the external medium (Gu *et al.*, 1998) and PTTH-containing neural extracts failed to stimulate ecdysteroid synthesis by *Drosophila* ring glands in the absence of external Ca^{2+} (Henrich, 1995). The importance of Ca^{2+} influx to PTTH-stimulated ecdysteroid synthesis was further demonstrated by the ability of the Ca^{2+} ionophore A23187 to stimulate ecdysteroidogenesis in *Manduca* (Smith and Gilbert, 1986) and *Bombyx* (Gu *et al.*, 1998) prothoracic glands.

Several studies using microfluorometric Ca^{2+} measurements explicitly verified the assumption that PTTH causes increases in prothoracic gland cytoplasmic free Ca^{2+} ($[Ca^{2+}]_i$) and that the external environment was the primary source of this Ca^{2+}. Birkenbeil (1996) showed that a PTTH preparation caused a rise in $[Ca^{2+}]_i$ in prothoracic glands of the wax moth, *G. mellonella*, while Birkenbeil and Dedos (2002) confirmed the interpretation that PTTH caused Ca^{2+} influx in *Bombyx* glands. In *Manduca*, Birkenbeil (1999, 2000) showed that PTTH preparations stimulated Ca^{2+} influx, and this work has been extended with pure *Manduca* recombinant PTTH (Fellner, Rybczynski, and Gilbert, unpublished data).

The modes by which free Ca^{2+} enters the cytoplasm of prothoracic glands in response to PTTH stimulation has been addressed chiefly in *Manduca*, *Galleria*, and *Bombyx*. In *Manduca* and *Bombyx*, cationic lanthanum inhibited PTTH-stimulated ecdysteroid synthesis (Smith *et al.*, 1985; Birkenbeil and Dedos, 2002); lanthanum is a nonspecific blocker of many plasma membrane ion channels. Identification of the precise types of Ca^{2+} channels that function in PTTH signaling has proven difficult. The Ca^{2+} channel agonist Bay K8644, which activates voltage-gated Ca^{2+} channels, stimulated ecdysteroid synthesis in both *Manduca* and *Bombyx* prothoracic glands (Smith *et al.*, 1987b; Dedos and Fugo, 1999b) but it is not known how this compound interacts with PTTH-stimulated Ca^{2+} influx, i.e., is it additive, synergistic, or antagonistic? In *Manduca*, the L-type channel blocker nitrendipine partially inhibited PTTH-stimulated ecdysteroid synthesis by prothoracic glands (Smith *et al.*, 1987; Girgenrath and Smith, 1996). However, nitrendipine was not found to inhibit PTTH-stimulated Ca^{2+} influx by Birkenbeil (1996, 1999). To confuse the issue more, an inhibitory effect of nifedipine, another L-type channel blocker, was demonstrated by Fellner *et al.* (unpublished data) while Birkenbeil (1999) did not observe any effect of nifedipine. Birkenbeil did note an inhibitory effect of amiloride, a T-type Ca^{2+} channel blocker, on PTTH-stimulated Ca^{2+} influx, but, at the concentration used, amiloride affects other proteins in addition to the T-type Ca^{2+} channels. In *Bombyx*, similarly conflicting data have been obtained. The L-type channel inhibitors verapamil (Gu *et al.*, 1998) and nitrendipine (Dedos and Fugo, 2001) both inhibited PTTH-stimulated ecdysteroidogenesis in *Bombyx* prothoracic glands but nitrendipine had no apparent effect

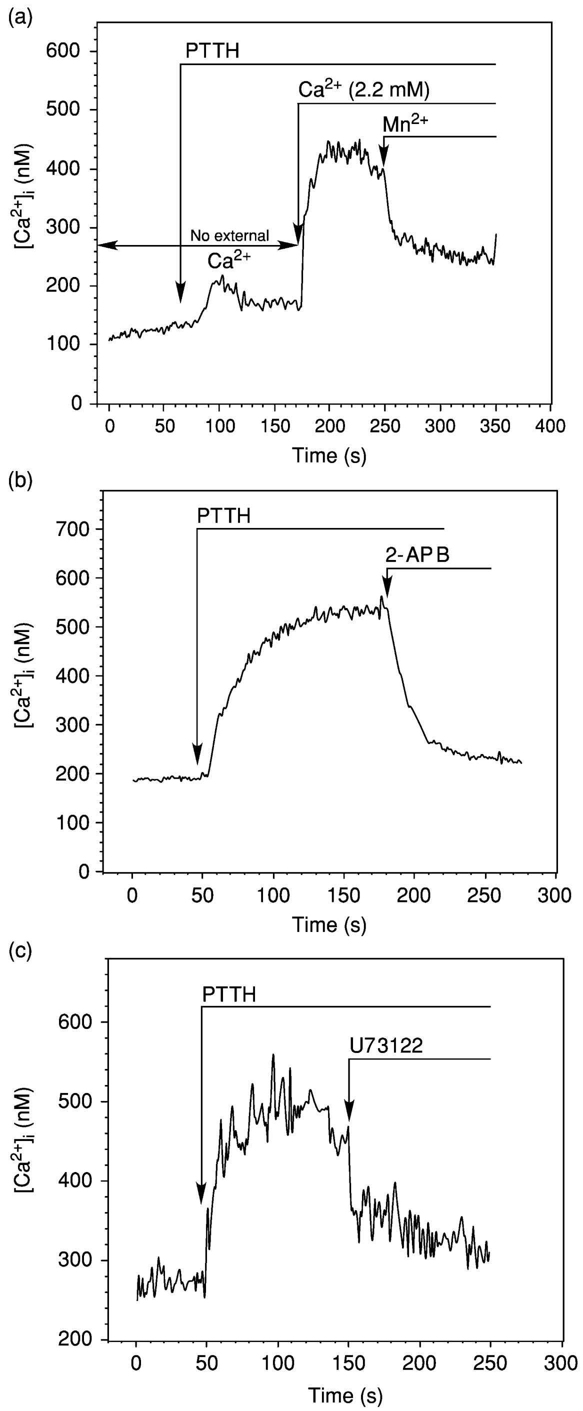

Figure 8 Free Ca^{2+} levels in prothoracic gland cells of *Manduca sexta* larvae, measured by fura-2 fluorescence. Data shown are representative plots from single cells. (a) The effect of PTTH on free cellular Ca^{2+} levels in the absence of external Ca^{2+}, and following the addition of Ca^{2+} to the incubation medium. The drop in free cellular Ca^{2+} levels following the addition of Mn^{2+} to the external medium is due to the entry of Mn^{2+} through store-operated channels. Mn^{2+}-dependent quenching of the Ca^{2+} fura-2 fluorescence indicates that the observed fluorescence results from Ca^{2+} binding to the fura, and not the simple accumulation of the dye within the cell. (b) 2-APB, an inhibitor of Ca^{2+} release from IP_3 gated stores on free cellular Ca^{2+} levels, truncates the PTTH-stimulated rise in free cellular Ca^{2+}. (c) U73122, an inhibitor of PLCβ, ablates the PTTH-stimulated rise in the concentration of free cellular Ca^{2+}. (Data from Fellner, Rybczynski, and Gilbert, unpublished data.)

on PTTH-stimulated cytoplasmic free Ca^{2+} (Birkenbeil and Dedos, 2002). The contribution of T-type Ca^{2+} channels to *Bombyx* PTTH signaling is not clear; two inhibitors of this channel class, bepridil and mibefradil, had no effect on PTTH-stimulated $[Ca^{2+}]_i$ changes, while the less specific amiloride inhibited $[Ca^{2+}]_i$ increases. These perplexing results may reflect methodological differences among the studies. It also seems likely that the identification of an insect channel type based purely on pharmacological reagents characterized in vertebrates may be risky (Girgenrath and Smith, 1996; Rybczynski and Gilbert, 2003).

Fellner *et al.* (unpublished data) investigated the kinetics of PTTH-stimulated increases in $[Ca^{2+}]_i$ in *Manduca* prothoracic glands and found that PTTH caused a rapid increase in $[Ca^{2+}]_i$ with levels plateauing within ≈30 s to 1 min. Furthermore, when prothoracic glands were incubated in the absence of external Ca^{2+} a small, transient $[Ca^{2+}]_i$ peak was seen followed by a large peak if Ca^{2+} is added to the external medium (see **Figure 8a**). These results suggested that PTTH first causes a release of Ca^{2+} from internal stores followed by a larger influx of external Ca^{2+}, with the large influx of Ca^{2+} being due substantially to the opening of store-operated channels. Store-operated channels are Ca^{2+} channels that respond to increases in internal Ca^{2+} (see Clementi and Meldolesi, 1996). The compound 2-aminoethoxydiphenyl borate (APB), an inhibitor of Ca^{2+} release from IP_3-sensitive stores in the endoplasmic reticulum, inhibited the PTTH-stimulated increase of $[Ca^{2+}]_i$, indicating that PTTH acts through the IP_3 receptor (**Figure 8b**) TMB-8, a second inhibitor of the release of Ca^{2+} from internal stores, also greatly diminished the PTTH-stimulated increase of $[Ca^{2+}]_i$, thus confirming the early participation of internal Ca^{2+} stores in the PTTH signal transduction pathway. It must be noted that Birkenbeil (1996, 1999) did not observe TMB-8 inhibition of PTTH-stimulated Ca^{2+} influx in *Galleria* or *Manduca* prothoracic glands. The reason for this is unknown. The composite data indicate that PTTH-stimulated increases in $[Ca^{2+}]_i$ originated from two Ca^{2+} pools: (1) an internal, IP_3-controlled endoplasmic reticulum store and (2) the extracellular milieu. The participation of an IP_3-controlled endoplasmic reticulum store in the early events of PTTH-stimulated Ca^{2+} mobilization was further

confirmed by the ability of a phospholipase C inhibitor (U73122) to block or interrupt $[Ca^{2+}]_i$ increases (**Figure 8c**); phospholipase C activity is required to generate IP_3 from its PIP_2 precursor.

Entry from the extracellular pool proceeds through at least two types of channels. One is a store-operated channel and the second is a voltage-gated channel, probably of the L-type. The opening of the voltage-gated channel may result from changes in transmembrane potential caused by operation of the store-operated channels, but other factors cannot be ruled out. For example, *Drosophila* dihydropyridine-sensitive Ca^{2+}channel activity can be modulated by either PLC or protein kinase A signaling pathways (Gu and Singh, 1997).

These results with *Manduca*, including sensitivity to TMB-8, were largely congruent with those reached in a similar study utilizing *Bombyx* prothoracic glands (Birkenbeil and Dedos, 2002), although at least two differences existed. First, no small increase in $[Ca^{2+}]_i$ was actually noted when *Bombyx* glands were stimulated with PTTH under Ca^{2+}-free conditions; however, the time resolution of the *Bombyx* study was too coarse to detect a transient peak such as found in *Manduca*. Second, the rapidity with which PTTH-stimulated $[Ca^{2+}]_i$ reached maximal levels was considerably slower and more variable in *Bombyx* (from ≈ 2 to >10 min) than in *Manduca* (≈ 20 s to 1 min). The drawn-out nature of the *Bombyx* $[Ca^{2+}]_i$ response is surprising; when $[Ca^{2+}]_i$ increases are a primary response to receptor activation, the kinetics of $[Ca^{2+}]_i$ increases are generally rapid and temporally stereotyped. At present it is unclear whether the differences in $[Ca^{2+}]_i$ kinetics are consequences of variant research protocols or represent biological differences between the species, e.g., the ability of a reagent to pass through the basal lamina surrounding the prothoracic gland might vary between *Manduca* and *Bombyx*. Regardless of the differences, the *Bombyx* data are consistent with the interpretation that PTTH causes release of Ca^{2+} from internal pools, followed by the opening of store-operated channels and voltage-gated channels.

The existence of a PTTH-stimulated, small $[Ca^{2+}]_i$ peak in *Manduca,* and presumably in *Bombyx*, sensitive to APB and TMB-8 inhibition, suggested that inositol metabolism played a role in PTTH-stimulated signal transduction, i.e., the generation of IP_3 by phospholipase C (PLC) and the subsequent release of IP_3-sensitive endoplasmic reticulum Ca^{2+} stores. Support for this hypothesis came from both *Bombyx* and *Manduca*. In the silkworm, the phospholipase C inhibitor, 2-nitro-4-carboxyphenyl-*N*, *N*-diphenylcarbamate, blocked PTTH-stimulated ecdysteroidogenesis but had no effect on basal synthesis. In *Manduca*, the phospholipase C inhibitor U73122, likewise blocked PTTH-stimulated ecdysteroidogenesis and was without effect on basal production (Rybczynski *et al*., unpublished data). Smith and Gilbert (1989) postulated the participation of phospholipase C in PTTH-stimulated ecdysteroidogenesis but attempts to detect PTTH-stimulated increases in PIP_2 metabolites like IP_3 have not been successful (Girgenrath and Smith, 1996; Dedos and Fugo, 2001). The failure to detect IP_3 might reflect a difficult-to-detect, small and transient IP_3 peak, if the APB-sensitive change in $[Ca^{2+}]_i$ is any guide to IP_3 behavior in the prothoracic gland. Clearly, in light of the results obtained with phospholipase C inhibitors, the question of PTTH-stimulated IP_3 generation should be readdressed. Indirect evidence supporting the participation of the IP_3 pathway in ecdysteroidogenesis have also resulted from the study of *Drosophila* carrying mutations in the IP_3 receptor gene (Venkatesh and Hasan, 1997; Venkatesh *et al*., 2001). Mutations in this gene caused molting delays and larval lethality that could be partially reversed by feeding larvae food that contained 20-hydroxyecdysone.

PTTH may stimulate changes in $[Ca^{2+}]_i$ and in Ca^{2+}-dependent events indirectly, as well as directly through receptor interactions. Electrophysiological studies using *Manduca* prothoracic glands *in vitro* revealed that Ca^{2+}-dependent action potentials could spread from cell to cell (Eusebio and Moody, 1986). PTTH and signals from nerves (see Section 3.2.5.2) are candidate triggers for such action potentials, but whether or not this occurs *in vivo* is unknown. Gap junctions and intercellular bridges have been found in *Manduca* prothoracic glands and these structures may allow the spread of signaling molecules, like cAMP, among cells (Dai *et al*., 1994). Thus, Ca^{2+}-dependent action potentials, gap junctions, and intercellular bridges all could serve to synchronize the behavior of the prothoracic gland cells in response to PTTH or other hormones. Measurements of resting $[Ca^{2+}]_i$ in *Manduca* cells indicated that cells of the prothoracic gland are indeed heterogeneous (Fellner, Rybczynski, and Gilbert, unpublished data), but, as yet, the significance of cell-to-cell differences is unknown. If cells are heterogeneous *in vivo* in their sensitivity to PTTH or other signals, signal-spreading among cells could serve to make the whole prothoracic gland respond at signal levels set by the most responsive cells. Note that a synchronization of cellular responses could downregulate the prothoracic gland's response to PTTH just as readily as facilitate it.

Both Ca^{2+} ions and cAMP are second messengers, although there are many cases in which the generation of cAMP is dependent upon prior intracellular changes in $[Ca^{2+}]_i$. This is the case in the prothoracic gland, where a role for cAMP in PTTH-stimulated ecdysteroid synthesis was first suggested by measurements of adenylate cyclase activity and intracellular cAMP in glands synthesizing large versus small amounts of ecdysteroids (Vedeckis and Gilbert, 1973; Vedeckis *et al.*, 1974, 1976). An explicit demonstration of the role of cAMP in ecdysteroid synthesis was obtained a decade later when *Manduca* PTTH preparations were shown to stimulate cAMP synthesis in a Ca^{2+}-dependent manner, i.e., extracellular Ca^{2+} was required for PTTH-stimulated cAMP synthesis (Smith *et al.*, 1984, 1985, 1986b). Further data supporting the upstream position of $[Ca^{2+}]_i$ relative to cAMP in the PTTH transduction cascade derive from observations that calcium ionophore mimics PTTH in eliciting both steroid and cAMP synthesis (Smith *et al.*, 1985, 1986b). In addition, the cell-permeable cAMP analog dibutyryl cAMP, as well as agents that activate adenylyl cyclase and inhibit cAMP phosphodiesterase activity, all stimulated ecdysteroid synthesis in prothoracic glands incubated in Ca^{2+}-free medium (Smith *et al.*, 1985, 1986b). Note that these *Manduca* studies utilized a partially purified PTTH, but identical results were later obtained with a recombinant PTTH (Gilbert *et al.*, 2000). Similar results have been obtained from *Bombyx* studies (Gu *et al.*, 1996, 1998; Dedos and Fugo, 1999b). Furthermore, *Bombyx* prothoracic glands stimulated with PTTH under Ca^{2+}-replete conditions continued to secrete ecdysteroids at elevated levels even after transfer to a Ca^{2+}-free medium (Birkenbeil and Dedos, 2002). Thus, if sufficient cAMP has been synthesized, extracellular Ca^{2+} is apparently no longer needed, at least under short-term *in vitro* conditions; any Ca^{2+}-dependent events that occur subsequent to cAMP generation must depend on $[Ca^{2+}]_i$ for time intervals of at least 2 h, a common *in vitro* incubation period.

The importance of cAMP in PTTH-stimulated ecdysteroid synthesis has been demonstrated in several studies. In *Manduca*, multiple analyses demonstrated that cell-permeable, excitatory cAMP analogs stimulated ecdysteroid synthesis (Smith *et al.*, 1984, 1985; Smith and Gilbert, 1986; Rybczynski and Gilbert, 1994). Furthermore, an antagonist form of cAMP (Rp-cAMP) substantially inhibited PTTH-stimulated ecdysteroidogenesis (Smith *et al.*, 1996). Excitatory cAMP analogs stimulated ecdysteroid synthesis in *Bombyx* prothoracic glands as well (Gu *et al.*, 1996, 1998; Dedos and Fugo, 1999c).

Adenylyl cyclase, which synthesizes cAMP from ATP, is found in multiple forms in vertebrates. The activity of these forms may be stimulated or inhibited by, or be insensitive to, G proteins or Ca^{2+}-calmodulin. In *Drosophila*, there appear to be nine isoforms of adenylyl cyclase, although five of these may be restricted to the male germline (Cann *et al.*, 2000). Meller *et al.* (1988, 1990) found that the *Manduca* prothoracic gland expresses Ca^{2+}/calmodulin-dependent adenylate cyclase activity that exhibits a developmental shift in some characteristics. Either of two calmodulin antagonists inhibited nearly all cyclase activity in membrane preparations (Meller *et al.*, 1988), suggesting that the vast majority, if not entirety, of gland adenylate cyclases are calmodulin-dependent. GTP-γ-S, a poorly hydrolyzable GTP analog, stimulated cyclase activity in both larval and pupal membrane preparations; however, in larval glands, GTP-γ-S was not effective without the simultaneous presence of calmodulin. This developmental switch in the characteristics of gland cyclase activity occurred about day 5 of the fifth larval instar, just prior to the beginning of the large premolt ecdysteroid peak. The switch was also characterized by changes in cyclase sensitivity to cholera toxin and NaF, two factors that interact with G proteins (Meller *et al.*, 1990). It is not known if the change in cyclase characteristics represents a change in cyclase isoform, a posttranslational modification, or a shift in the expression of proteins that interact with cyclase. In *Bombyx* prothoracic gland membrane preparations, calmodulin, Gpp(NH)p (a GTP analog) and NaF stimulated adenylate cyclase activity, while GDB-β-S, a GDP analog, inhibited activity (Chen *et al.*, 2001). NaF and calmodulin effects on cyclase activity were additive rather than synergistic, suggesting that both G protein- and calmodulin-dependent adenylate cyclases exist in the *Bombyx* prothoracic gland. It remains to be determined which of these putatively different adenylate cyclases is coupled to the PTTH signal transduction cascade. However, both *Bombyx* and *Manduca* prothoracic glands respond to cholera toxin with increased ecdysteroidogenesis (Girgenrath and Smith, 1996; Dedos and Fugo, 1999c); an increase in cellular cAMP levels was also measured in *Bombyx* glands. These data suggested that a $G\alpha_s$ protein might be coupled to the PTTH receptor.

Many, if not all, intracellular signaling systems exhibit downregulation after a time, with signaling intermediates returning to basal levels. During continuous presence of PTTH, $[Ca^{2+}]_i$ levels persisted above basal for at least 25 min in *Bombyx* prothoracic glands, with a peak at about 15 min after initiating PTTH stimulation; after transfer of

stimulated glands to PTTH-free conditions, $[Ca^{2+}]_i$ levels remained elevated for at least 20 min (Birkenbeil and Dedos, 2002). Similar $[Ca^{2+}]_i$ data are not available for *Manduca* prothoracic glands. Thus, how long $[Ca^{2+}]_i$ remains elevated during or after PTTH stimulation is not known. In the prothoracic glands of *Galleria* sixth and seventh (final) larval instars, Birkenbeil (1996) found developmental changes in $[Ca^{2+}]_i$, with peaks co-occurring coincident with peaks of *in vitro* ecdysteroid production. This observation suggested a relatively slow return to basal conditions and/or nonadaptation to continuous PTTH stimulation. In contrast, intracellular Ca^{2+} was essentially constant in glands of fifth instar *Manduca* larvae (Birkenbeil, 1999). The mechanisms by which prothoracic gland $[Ca^{2+}]_i$ is restored to the basal level have not been explicitly explored but presumably involve buffering by Ca^{2+}-binding proteins, reloading of internal stores and transport to the extracellular milieu.

The temporal profile of cAMP levels during PTTH stimulation of the prothoracic gland is also incomplete. PTTH elicited a rapid generation of cAMP in *Manduca* prothoracic glands, readily detectable within 2 min of applying PTTH and peaking after 5 min (Smith *et al.*, 1984). Elevated cAMP levels persisted for at least 20 min, with continuous PTTH exposure. Data from *Bombyx* prothoracic glands were similar, with a rapid rise in cAMP that reached a maximum at 10 min and continued at about twice basal for at least an hour (Gu *et al.*, 1996). Analysis of cAMP levels in *Manduca* prothoracic glands during the fifth (final) larval instar revealed a large maximum occurring at about the time of the commitment peak in ecdysteroid production (Vedeckis *et al.*, 1976), suggesting, as is the case for $[Ca^{2+}]_i$, a slow return to basal levels following stimulation and/or nonadaptation to continuous PTTH stimulation. Initially surprising were the relatively low levels of gland cAMP observed during the premolt period of high ecdysteroid production several days later (but see discussion immediately following).

Intracellular cAMP levels are a product of synthesis and breakdown. The puzzlingly low cAMP *in vivo* levels found during the premolt ecdysteroid peak (Vedeckis *et al.*, 1976), as well as in *Manduca* glands stimulated *in vitro* with PTTH at this stage and later (Smith and Gilbert, 1986; Smith and Pasquarello, 1989), appear to result chiefly from developmental differences in phosphodiesterase activity. Analysis of cAMP phosphodiesterase activity revealed a nearly six-fold increase from a minimum on days 3 and 4 to a peak just prior to pupal ecdysis; at the time of the large, premolt ecdysteroid peak, when PTTH signaling is presumably high also, phosphodiesterase activity was ≈5 times the minimum (Smith and Pasquarello, 1989). This observation suggested that the importance of the cAMP pathway in PTTH signal transduction was greatly diminished in late larval and pupal glands (Vedeckis *et al.*, 1976). This proved clearly not to be the case, as demonstrated by the inhibitory action of a cAMP antagonist on PTTH-stimulated pupal ecdysteroid synthesis (Smith *et al.*, 1996).

3.2.4.3. Protein Kinases and Phosphatases

A very common, if not universal, response to increases in second messengers is the modulation of protein kinases and phosphatase activities. In this section, known and hypothesized kinase and phosphatase contributors to PTTH signaling are discussed. These enzymes are discussed separately, perhaps giving a linear view of their participation in the PTTH signal transduction cascade. This is clearly not the case and the enzyme-by-enzyme approach is followed merely to provide a structure to the discussion, not to imply simplicity of the pathway.

3.2.4.3.1. Protein kinase A Two isoforms of cAMP-dependent protein kinase A (PKA; types I and II) have been found in the *Manduca* prothoracic gland, with the majority of the activity (≥95%) attributable to the type II isoform (Smith *et al.*, 1986b). PTTH-dependent stimulation of PKA activity was found in both larval and pupal glands, although the addition of a phosphodiesterase inhibitor was necessary to measure PTTH-dependent PKA activity in the latter. The requirement of a phosphodiesterase inhibitor to measure PTTH-dependent PKA activity in pupal glands was not surprising, given the rapid metabolism of cAMP at this stage, as discussed above (see Section 3.2.4.2). PTTH stimulated PKA activity rapidly, with a patent increase above controls following 3 min of exposure, and with elevated levels still evident after 90 min (Smith *et al.*, 1986b). PKA is composed of two subunits: one catalytic and the other regulatory. In prothoracic glands of early fifth larval instars of *Manduca*, the catalytic subunit remains relatively constant per mg protein for the first 4 days while the regulatory subunit increases approximately three-fold (Smith *et al.*, 1993). This may insure that PKA is only activated when a fairly high threshold of cAMP has accumulated in response to PTTH (Smith *et al.*, 1993), but this hypothesis is assuredly tentative, pending information not currently available, on the relative abundances of the catalytic and regulatory subunits at other stages of development.

The rapid activation of PKA in response to PTTH stimulation suggests that PKA plays a proximate role in the control of PTTH-stimulated steroidogenesis. The effects of agonist and antagonist cAMP homologs is supportive but not conclusive evidence for this interpretation, since there are other cellular targets for cAMP besides PKA. For instance, in mammals, cAMP-dependent guanine nucleotide exchange factors, which activate small G proteins, have been described (Kawasaki *et al*., 1998). These proteins can stimulate phosphorylation events, including the activation of the 70-kDa S6 kinase, a known element in PTTH action (see below), and a search of the *Drosophila* genome data base suggests that insects may possess one or more homologs to these exchange factors (data not shown). However, the PKA inhibitor H89 is effective at blocking PTTH-stimulated ecdysteroid synthesis in *Manduca* glands, albeit at fairly high doses, again implicating PKA as a regulatory factor in this pathway (Smith *et al*., 1996). The *in vivo* substrates for PTTH-activated PKA are poorly known. PTTH, dibutyryl cAMP, and Ca^{2+} ionophore all stimulate phosphorylation of a 34-kDa protein in *Manduca* prothoracic glands (Rountree *et al*., 1987, 1992; Combest and Gilbert, 1992; Song and Gilbert, 1994) that has been identified as the S6 ribosomal protein (Song and Gilbert, 1995). However, it is unclear that S6 is directly phosphorylated by PKA. When the (mammalian) catalytic subunit of PKA, or cAMP, was added to prothoracic gland homogenates, the phosphorylation of S6 was enhanced (Smith *et al*., 1987a; Rountree *et al*., 1992; Combest and Gilbert, 1992), indicating that S6 was a potential PKA substrate. However, in intact cells, the situation may be different since the immunosuppressive agent rapamycin was able to block PTTH-stimulated S6 phosphorylation (Song and Gilbert, 1994, 1995). Rapamycin acts via formation of a protein complex that inhibits p70 S6 kinase activity and PKA is neither a known substrate for rapamycin nor a component of the rapamycin–protein complex (see Section 3.2.4.4).

3.2.4.3.2. Protein kinase C The possibility that protein kinase C (PKC) was involved in the PTTH-stimulated ecdysteroid synthesis was first addressed, with negative results, by Smith *et al*. (1987a), using the potent PKC activator phorbol myristate acetate (PMA). A 90-min incubation with PMA had no effect on *Manduca* steroidogenesis, either alone or in conjunction with PTTH (see also Smith, 1993). However, in *Bombyx*, PMA boosted prothoracic gland ecdysteroid synthesis after 5 h of treatment, but no effect was apparent after 2 h (Dedos and Fugo, 2001), suggesting that PKC did not play an acute role in steroidogenesis. Furthermore, studies on inositol metabolism in both *Manduca* and *Bombyx* failed to find PTTH-related generation of PIP_2 metabolites (see Section 3.2.4.2). Diacyl glycerol (DAG), one of these metabolites, is an activator of PKCs and is formed in a 1 : 1 ratio with IP_3. The apparent absence of IP_3 suggested that DAG was also absent and hence that PKCs were not involved in PTTH action. Nevertheless, three lines of evidence do indicate that a PKC is part of the signal transduction network of PTTH, and that it occupies an early and important position in regulating prothoracic gland ecdysteroidogenesis. First, the PKC inhibitor chelerythrine Cl inhibited PTTH-stimulated ecdysteroid synthesis by both *Bombyx* (Dedos and Fugo, 2001) and *Manduca* prothoracic glands (**Figure 9a**) (Rybczynski and Gilbert, unpublished data); PTTH stimulated ERK phosphorylation was also inhibited (**Figure 9a**). Second, PTTH-stimulated the phosphorylation of several (unidentified) prothoracic gland proteins, as recognized by an antibody against phosphorylated PKC substrate sequences (**Figure 9b**), and chelerythrine Cl inhibited these phosphorylations (data not shown) (Rybczynski and Gilbert, unpublished data). Third, although measurable changes in IP_3 or other PIP_2 metabolites have not been detected following PTTH stimulation, phospholipase C inhibitors blocked PTTH-stimulated ecdysteroid synthesis in *Bombyx* (2-nitro-4-carboxyphenyl-N, *N*-diphenylcarbamate: Dedos and Fugo, 2001) and *Manduca* (U73122: Fellner *et al*., unpublished data) prothoracic glands (**Figure 9c**). U73122 also inhibited PTTH-stimulated ERK phosphorylation (**Figure 9c**) and the release of Ca^{2+} from IP_3-sensitive stores (see Section 3.2.4.2). These data suggest that PTTH stimulates inositol metabolism and activates PKCs, but the inositol increases are too small or transient to have been detected. Intracellular compartmentalization of early acting components of the signal transduction system might make small changes biologically meaningful and eliminate the need for large-scale intracellular increases in IP_3 or DAG.

The identity and function of proteins phosphorylated by PKC in response to PTTH stimulation of the prothoracic gland are currently unknown. PKCs can modulate the function of a wide variety of proteins including ion channels (see Shearman *et al*., 1989), MAP kinases (Suarez *et al*., 2003), plasma membrane receptors (Medler and Bruch, 1999), cytoskeletal elements (Gujdar *et al*., 2003), and nuclear proteins (Martelli *et al*., 2003). The observation that some putative PKC phosphorylations took place only after several hours of PTTH stimulation

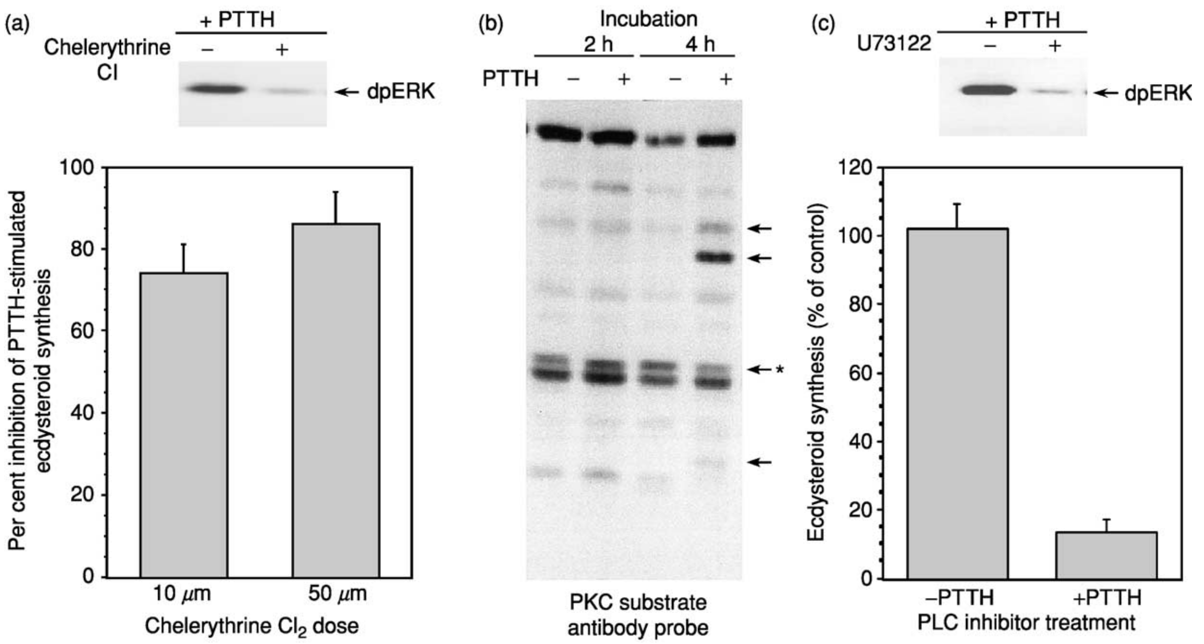

Figure 9 Evidence for the involvement of PKC and PLC in PTTH-stimulated events in the larval prothoracic gland of *Manduca sexta*. Ecdysteroids were measured with a radioimmunoassay and protein phosphorylation detected following SDS-PAGE of gland proteins, using phospho-specific antibodies and chemiluminescence reagents. (a) Chelerythrine Cl, an inhibitor of PKC, blocks PTTH-stimulated ecdysteroid synthesis (lower panel) and ERK phosphorylation (upper panel). Chelerythrine Cl had no effect on basal ecdysteroid synthesis and ERK phosphorylation (data not shown). (b) PTTH stimulates the phosphorylation of proteins recognized by an antibody against putative PKC phosphorylation substrate sites. Glands were incubated for up to 4 h ± PTTH. (c) U73122, an inhibitor of PLCβ, blocks PTTH-stimulated ecdysteroid synthesis, without affecting basal synthesis (lower panel). U73122 also inhibits PTTH-stimulated ERK phosphorylation (upper panel) but basal ERK phosphorylation is unaffected (data not shown). (Data from Rybczynski, Fellner, and Gilbert, unpublished data.)

(Figure 9b) suggested that PKC might be involved in the long-term effects of PTTH, such as transcription, as well as in the acute regulation of steroid synthesis. The position of PKC in the PTTH signaling hierarchy has not been determined but, given a probable requirement for DAG, it seems likely that PKC is among the first intracellular components to be called into action. This hypothesis is supported by the observations that (1) inhibition of PKC activity prevented PTTH-dependent ecdysteroid synthesis and (2) inhibition of PKC activity prevented PTTH-dependent MAP kinase phosphorylation (see below), i.e., PKC is upstream of MAP kinases (Rybczynski and Gilbert, unpublished data). The time course of PKC activity in the PTTH signal transduction network may be extended given the observed late appearance of some putative PKC phosphorylation events (Figure 9b).

3.2.4.3.3. Extracellular signal-regulated kinase The mitogen-activated protein kinases (MAP kinases) are a family of related proteins that are activated by a wide variety of extracellular signals, ranging from growth factors and peptide hormones to heat and osmotic stresses. MAP kinases, in turn, regulate a wide variety of intracellular processes from microtubule stability and protein synthesis to transcription. There are several families of MAP kinases, which are organized into three-level signaling modules, i.e., a MAP kinase, a MAP kinase kinase (MEK), and a MAP kinase kinase kinase (MEKK or MAP3K) (see Lewis *et al.*, 1998; Kyriakis, 2000). Perhaps the most studied of the MAP kinase modules is the extracellular signal-regulated kinase (ERK) cascade. This module typically starts with a protein called RAF, and proceeds through a MEK to the ERK protein(s); in mammals there are two ERKs while *Drosophila* and *Manduca* appear to express a single ERK (see Lewis *et al.*, 1998; Biggs and Zipursky, 1992; Rybczynski *et al.*, 2001). A number of proteins lie upstream from RAF, the small G protein RAS is a frequent but not ubiquitous activator of RAF, which itself may lie downstream of G protein-coupled receptors, tyrosine kinase receptors, or cytokine receptors (see Lewis *et al.*, 1998). MEKKs and MEKs are activated by single phosphorylations while ERKs require a dual phosphorylation on threonine and tyrosine residues for activity.

A PTTH stimulation of the ERK pathway in larval *Manduca* prothoracic glands was shown

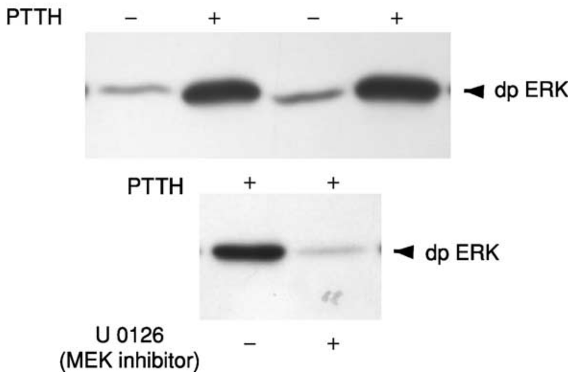

Figure 10 PTTH stimulates ERK phosphorylation in the larval prothoracic gland of *Manduca sexta* (upper panel) that is blocked by the MAPK/ERK kinase inhibitor U0126 (lower panel). ERK phosphorylation was detected following SDS-PAGE of gland proteins, using an antiphosphorylated ERK antibody and chemiluminescence reagents. (Adapted from Rybczynski, R., Bell, S.C., Gilbert, L.I. **2001**. Activation of an extracellular signal-regulated kinase (ERK) by the insect prothoracicotropic hormone. *Mol. Cell. Endocrinol. 184*, 1–11.)

recently (Rybczynski *et al.*, 2001) using activity assays, inhibitors of ERK phosphorylation, and antibodies that recognize the dually phosphorylated state (see **Figure 10**). This study revealed that PTTH caused a rapid but transient increase in ERK phosphorylation and that inhibitors of ERK activation blocked both basal and PTTH-stimulated ecdysteroid syntheses. The data suggested that ERKs might be involved in regulating some aspects of the acute PTTH response in prothoracic glands. Further examination showed that PTTH-stimulated ERK phosphorylation was primarily a larval gland response. As *Manduca* larvae progressed through the fifth instar, PTTH-stimulated phosphorylation in the prothoracic gland declined until it was undetectable in pupal glands (Rybczynski and Gilbert, 2003). Concurrently, ERK levels declined in the glands but the basal levels of phosphorylation increased in response to unknown factors. These two phenomena combined to cause the aforementioned decline in PTTH-stimulated ERK phosphorylation. Rybczynski and Gilbert (2003) also found that PTTH-stimulated ERK phosphorylation occurred via a Ca^{2+}-dependent pathway but not one that was cAMP-dependent. Some PKC isotypes require Ca^{2+} for activation and thus are candidates for the regulation of the ERK cascade. As discussed above, PKC inhibition resulted in a block of PTTH-stimulated ERK phosphorylation (**Figure 8c**). In fact, PKC may directly activate RAF, the first component of the ERK phosphorylation module, without the participation of RAS (see Liebman, 2001). However, PKC might control ERK phosphorylation in a less specific manner if PKC regulates PTTH-stimulated Ca^{2+} channel opening. Of note in this regard is the observation that PKC modulation of dihydropyridine-sensitive Ca^{2+} channels occurs in *Drosophila* tissues (Gu and Singh, 1997). The protein kinase Pyk2, which can be activated by increases in $[Ca^{2+}]_i$ and by PKC (Lev *et al.*, 1995), is also a reasonable candidate to be an upstream regulator of the ERK cascade.

The list of potential targets of ERK phosphorylation is long and encompasses transcription factors, steroid and growth factor receptors, various membrane-associated proteins, cytoskeletal proteins, kinases, and proteins involved in regulating translation (see Grewal *et al.*, 1999). Studies to discover PTTH-related ERK phosphorylation targets in the prothoracic gland are currently underway but no conclusive identifications can be made at this time. In most cell types, some fraction of dually phosphorylated ERKs migrate into the nucleus where they modulate transcription; no conclusive information about the prothoracic gland on this topic is presently available. Preliminary cell fractionation experiments suggested that dually phosphorylated ERKs do indeed move into the prothoracic gland cells' nuclei following PTTH stimulation (Rybczynski and Gilbert, unpublished data); however, the basal lamina surrounding the gland and the very large nuclei make clean subcellular fractions difficult to obtain and the conclusion must be considered tentative.

3.2.4.3.4. p70 S6 kinase The S6 protein is a prominent ribosomal phosphoprotein that can be phosphorylated by PKA and a 70-kDa S6 kinase (p70S6K) (Palen and Traugh, 1987). S6 phosphorylation is a frequent and presumably important event in various intercellular signaling pathways (see Erickson, 1991; Volarevic and Thomas, 2001). Phosphorylation of S6 by p70S6K, but apparently not by PKA, can increase the rate of translation of some mRNAs (Palen and Traugh, 1987). PTTH has long been known to induce the phosphorylation of a ≈34-kDa protein in prothoracic glands of *Manduca*, which was hypothesized to be S6 (see Gilbert *et al.*, 1988); this identification proved to be correct (see Section 3.2.4.4).

Song and Gilbert (1994) showed that p70S6K was responsible for PTTH-stimulated S6 phosphorylation in *Manduca* prothoracic glands. Using the macrolide immunosuppressant rapamycin, which blocks p70S6K phosphorylation-dependent kinase activity (see Dufner and Thomas, 1999), they found that PTTH-stimulated phosphorylation of an S6 peptide substrate was inhibited by rapamycin,

when tested with an S6K1-enriched protein fraction prepared from glands treated with both PTTH and rapamycin. Furthermore, rapamycin inhibited PTTH-stimulated ecdysteroid synthesis at low (nM) concentrations. These observations also implicate the participation of at least two additional proteins in the PTTH transduction cascade, although direct proof of their activity remains to be obtained. One is the phosphoinositide 3OH-dependent kinase (PI3K) and the second is a protein termed, among others, TOR (target of rapamycin; the *Drosophila* gene is called *dtor*) and *frap* (FKBP12-rapamycin-associated protein). TORs are proteins that contain a kinase domain similar to that of PI3K; their activity is inhibited when rapamycin binds to the small protein FKBP, forming an inhibitory complex that interacts with TORs (see Fumagalli and Thomas, 2000). Both PI3K and TOR positively regulate p70S6K activity. It is likely that another level of proteins is interposed between p70S6K and PI3K, such as the atypical PKCs (see Fumagalli and Thomas, 2000). TORs probably interact directly with p70S6K and also inhibit phosphatases that downregulate p70S6K activity (see Fumagalli and Thomas, 2000). Activation of PI3K by PTTH might take place via several intermediary proteins, such as RAS, or the βγ subunit of G proteins (see Coffer, 2000). The regulation of TOR function, in the context of PTTH, is more problematic. It may be activated by PI3K, perhaps via an intermediate kinase, but the regulation of TORs is incompletely understood (see Raught *et al.*, 2001; Abraham, 2002).

3.2.4.3.5. Tyrosine kinases Many intercellular signaling molecules evoke a series of protein phosphorylations on tyrosine residues within the target tissues. Tyrosine kinases include both intracellular proteins as well as membrane-spanning receptors. The possibility that PTTH signal transduction involves tyrosine kinase has been addressed in part by Smith *et al.* (2003). Their work revealed that PP1, an inhibitor of the Src tyrosine kinase, repressed PTTH-stimulated cAMP and ecdysteroid synthesis in *Manduca* prothoracic glands. PP1 did not appear to interact with adenylate cyclase, since forskolin was still able to stimulate cAMP production in the presence of PP1. This result suggested that a Src kinase might act very early in PTTH signaling, perhaps at the level of Ca^{2+} mobilization. Indeed, tyrosine kinases can activate phospholipases, generating IP_3 and raising $[Ca^{2+}]_i$ via the IP_3 receptor/Ca^{2+} channel (see Rhee, 2001); tyrosine kinases can also directly activate the IP_3 receptor/Ca^{2+} channel through phosphorylation (Jayaraman *et al.*, 1996). Another intriguing possibility is that stimulation of the PTTH receptor, if it is indeed a GPCR, might transactivate a tyrosine receptor kinase via G proteins and other intermediates, and consequently recruit some or all of the signaling pathway of a completely different receptor class (see Luttrell *et al.*, 1999; Wetzker and Bohmer, 2003). Perhaps relevant to this scenario is the observation that an antibody against the vertebrate insulin receptor, a tyrosine kinase receptor, cross-reacted with a protein of appropriate molecular weight in the prothoracic gland (Smith *et al.*, 1997) and a second antibody against tyrosine-phosphorylated proteins indicated that PTTH stimulated the phosphorylation of a protein of the same molecular weight (Smith *et al.*, 2003). However, care must be taken in interpreting the effects of this single kinase inhibitor, since PP1, at the micromolar concentrations employed, might inhibit other kinases, including those in the ERK pathway (see Bain *et al.*, 2003).

3.2.4.4. Ribosomal Protein S6

Ribosomal protein S6 is a small (≈34 kDa) basic protein, present at one copy per 40S ribosome, that is located near the tRNA/mRNA binding site (see Fumagalli and Thomas, 2000). Phosphorylation of S6 is associated with mitogenic stimulation of non-dividing cells and occurs in vertebrate steroidogenic cells in response to factors such as FSH and TSH (Das *et al.*, 1996; Suh *et al.*, 2003); of course, FSH and TSH have mitogenic effects as well as effects on hormone synthesis. S6 phosphorylation at six serine residues near the C-terminal of the protein has been correlated with the selective increase of certain mRNAs, especially those containing polypyrimidine tracts near the transcription initiation site (see Erickson, 1991; Fumagalli and Thomas, 2000; Meyuhaus and Hornstein, 2000; Volarevic and Thomas, 2001).

Rountree *et al.* (1987) and others (see Section 3.2.4.3.1) discovered that PTTH stimulates the phosphorylation of a ≈34 kDa-protein in *Manduca* prothoracic glands that was hypothesized to be the S6 ribosomal protein. Song and Gilbert (1994, 1995, 1997) confirmed this identification by using the p70S6K inhibitor rapamycin and, more rigorously, by two-dimensional analysis of ribosomal proteins (see **Figure 11**). As discussed earlier, they found that rapamycin blocked S6 phosphorylation and ecdysteroid synthesis; furthermore, rapamycin inhibited the accumulation of specific, newly synthesized proteins, including a heatshock 70-kDa cognate protein (Song and Gilbert, 1995), which had been hypothesized to be necessary for PTTH-stimulated ecdysteroid synthesis (Rybczynski and Gilbert, 1994, 1995a; see below).

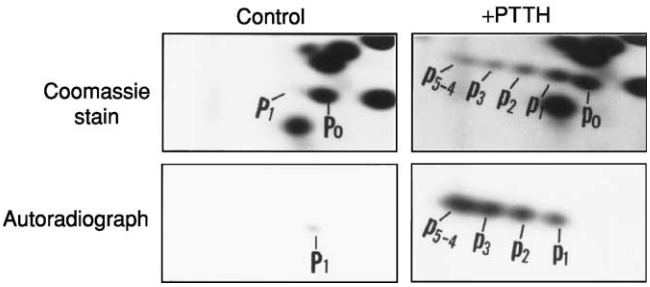

Figure 11 PTTH stimulates the phosphorylation of ribosomal protein S6 in the prothoracic gland of *Manduca sexta*. The upper two panels show the effect of PTTH on the migration pattern of the S6 protein (labeled P_0 to $P_{5–4}$) in two-dimensional gel analyses of ribosomal proteins, as visualized with Coomassie Blue staining. The lower two panels show the effect of PTTH on the migration pattern of the S6 protein, as visualized with autoradiography of ^{32}P-labeled proteins, following two-dimensional gel analyses of ribosomal proteins. The data reveal that up to five sites on S6 are phosphorylated following the stimulation of prothoracic glands with PTTH. (Adapted from Gilbert, L.I., Song, Q., Rybczynski, R. **1997**. Control of ecdysteroidogenesis: activation and inhibition of prothoracic gland activity. *Invert. Neurobiol. 3*, 205–216.)

cDNA cloning of the *Manduca* S6 mRNA revealed that the sequence coded for a polypeptide of ≈ 29 000 MW, with an estimated isoelectric point of 11.5 (Song and Gilbert, 1997). Like the mammalian S6 proteins, the *Manduca* sequence contained a cluster of six serines in the final (C-terminal) 20 amino acids. Phosphoamino acid analysis indicated that, following PTTH stimulation, the *Manduca* S6 protein was phosphorylated solely on serines. The two-dimensional analysis of ribosomal proteins showed that PTTH-stimulation resulted in phosphorylation of up to five sites; nonstimulated glands yielded an S6 with an apparent single phosphorylation (Song and Gilbert, 1995, 1997). The location of the PTTH-stimulated serine phosphorylations is not known since, in addition to the six terminal serines, the *Manduca* protein was deduced to contain an additional 10 residues. The combination of Northern blotting, using the S6 cDNA as a probe, and immunoblotting, using polyclonal antibodies against the S6 protein terminus, showed that S6 RNA and protein levels in the prothoracic gland were not correlated (Song and Gilbert, 1997). S6 RNA per unit total RNA was highest in the first 3 days of the fifth instar and decreased linearly to a much lower level by day 7; this low level persisted through day 4 of pupal life, interrupted only by a minor increase on the first day following pupal ecdysis. In contrast, S6 proteins showed two peaks of abundance. The first occurred on days 6 and 7 of the fifth instar, when the prothoracic gland is beginning the large surge of ecdysteroid synthesis that precedes the larval–pupal molt. The second peak fell on days 3 and 4 of pupal–adult development, the beginning of the large pupal–adult period of ecdysteroid synthesis. As a control, S6 protein levels in the fat body were assayed. These showed no relationship to S6 in the prothoracic gland or to hemolymph ecdysteroid titers. Rather, S6 protein in fat body showed a steady decline from the beginning to the end of the fifth instar and then fairly constant low levels through day 4 of pupal–adult development. These data suggested that S6 levels might be a controlling factor in supporting high levels of ecdysteroid synthesis.

Although these composite data strongly support the notion that the PI3K/TOR–p70S6K–S6 axis is essential for PTTH-stimulated ecdysteroid synthesis to occur, there are some puzzling data that do not readily fit this scheme. Both Rountree *et al.* (1987) and Smith *et al.* (1987a) discovered that, like PTTH, a cAMP analog (dibutyryl cAMP (dbcAMP)) stimulated S6 phosphorylation and Rountree *et al.* (1987) found that JH and a JH analog inhibited S6 phosphorylation in glands studied *in vitro* (Rountree *et al.*, 1987). However, under the same *in vitro* conditions, JH had no effect on PTTH-stimulated cAMP synthesis and ecdysteroid synthesis (Rountree and Bollenbacher, 1986). A second puzzling observation, revolving again around cAMP, stems from the study of the effects of rapamycin on steroidogenesis. As described above, rapamycin inhibits both PTTH-stimulated S6 phosphorylation, and ecdysteroidogenesis. However, dbcAMP was able to override the rapamycin block and stimulate ecdysteroid synthesis to the usual levels above basal, even though rapamycin blocked the dbcAMP-dependent S6 phosphorylation (Song and Gilbert, 1994). These two sets of data suggest that a vigorous, six-site S6 phosphorylation response may not be required to support PTTH-stimulated ecdysteroid synthesis. In this respect, it would be interesting to use the more sensitive two-dimensional gel analysis of ribosomal proteins to determine if JH and rapamycin blocked all phosphorylations above the basal level; it might be that the single-dimension gel

analysis used was not sensitive enough to detect partial S6 phosphorylation in these experiments. It is also possible that there are alternate pathways by which PTTH stimulates ecdysteroid synthesis and that these pathways can substitute for the presumably default S6-dependent one. For instance, activation of the ERK pathway can also upregulate protein translation in some cells (see Grewal *et al.*, 1999).

3.2.4.5. Translation and Transcription

In vertebrate steroidogenic tissues, the final signal transduction step in peptide-regulated steroid hormone production is the rapid translation of one or more proteins. In these taxa, two proteins, StAR (steroidogenic acute regulatory protein) and DBI (diazepam-binding inhibitor), facilitate the delivery of cholesterol across the mitochondrial membrane to the side-chain cleavage P450 enzyme, which converts cholesterol to pregnenelone (see Stocco and Clark, 1997; Papadopoulos *et al.*, 1997; **Chapter 3.3**). This step is rate limiting and is alleviated by rapid translation of StAR and/or DBI that is stimulated by a peptide hormone such as adrenocorticotropic hormone (ACTH). A *Manduca* DBI homolog has been cloned and evidence suggests a role for DBI in basal ecdysteroid synthesis (Snyder and Feyereisen, 1993; Snyder and Van Antwerpen, 1998), but experiments to explicitly test its role in acute PTTH-stimulated ecdysteroidogenesis have yet to be performed. Analysis of the *Drosophila* and *Anopheles* genome databases indicates that an insect protein with close homology to the StAR-like vertebrate protein MLN64 exists but the similarity of the insect protein to StAR itself is lower. MLN64 contains a region homologous to the cholesterol-binding region of StAR (see **Chapter 3.3**) but the insect protein sequence contains a large interior region that has no vertebrate counterpart and *in situ* hybridizations in *Drosophila* indicate that expression is not limited to the ring gland (see **Chapter 3.3**).

In insects, it is clear that PTTH-stimulated ecdysteroid synthesis also requires translation, as revealed by the ability of translation inhibitors like cycloheximide and puromycin to block such ecdysteroid synthesis (Keightley *et al.*, 1990; Kulesza *et al.*, 1994; Rybczynski and Gilbert, 1995a); translation inhibitors have no effect on basal ecdysteroid synthesis, under standard *in vitro* protocols. In *Drosophila*, the movement of an ecdysteroid precursor(s) between intracellular compartments (endoplasmic reticulum and mitochondrion) probably involves a carrier protein, although the necessity of translation in this species has not been demonstrated (Warren and Gilbert, 1996; Warren *et al.*, 1996).

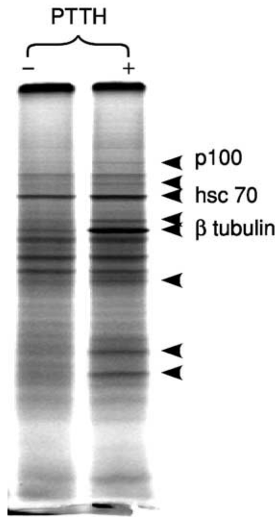

Figure 12 PTTH stimulates the synthesis of specific proteins in the prothoracic gland of *Manduca sexta*. Glands were incubated with ^{35}S-methionine ± PTTH for 1 h and then subjected to SDS-PAGE and autoradiography. The arrowheads indicate newly synthesized proteins whose accumulation in the prothoracic gland is upregulated by PTTH. Hsc 70, β tubulin and p100 were identified in the first studies on this system (Rybczynski and Gilbert 1994, 1995a; 1995b); the additional PTTH-regulated translation products were only detected after further refinement of the SDS-PAGE conditions (Rybczynski and Gilbert, unpublished data).

Analysis of protein synthesis in *Manduca* prothoracic glands, using ^{35}S-methionine to label newly synthesized proteins, revealed that PTTH stimulated overall translation at most developmental stages and that some proteins, perhaps as many as 10, were differentially translated above this general increase (see **Figure 12**) (Keightley *et al.*, 1990; Rybczynski and Gilbert, 1994; Gilbert *et al.*, 1997). Two of these proteins have been identified and cloned: a β tubulin (Rybczynski and Gilbert, 1995a, 1998) and a 70-kDa heatshock cognate protein (hsc 70) (Rybczynski and Gilbert, 1995b, 2000). PTTH-stimulated synthesis of hsc 70 rose slowly and was prolonged, suggesting that hsc 70 might function as a chaperone in supporting translation, and in other long-term effects of PTTH not directly connected to acute changes in ecdysteroidogenesis, e.g., an hsc 70 protein appears to be necessary for proper function of the ecdysone receptor (Arbeitman and Hogness, 2000). PTTH-stimulated hsc 70 synthesis above basal at all stages examined during the fifth instar and pupal–adult development; peaks occurred on the third day of the fifth instar (V_3) and the first day of pupal–adult development (P_1) (Rybczynski and Gilbert, 1995b). In contrast, PTTH-stimulated β tubulin synthesis occurred

rapidly and was transitory, suggesting a more direct role in ecdysteroidogenesis for this cytoskeletal protein (Rybczynski and Gilbert, 1995a). Peaks in PTTH-stimulated β tubulin synthesis occurred on V_3 and P_1 (Rybczynski and Gilbert, 1995a), as observed for hsc 70. Indeed, treatment of pupal prothoracic glands with microtubule-disrupting drugs inhibited PTTH-stimulated ecdysteroid synthesis (Watson *et al.*, 1996) but this effect was not seen in larval glands (Rybczynski and Gilbert, unpublished data). Furthermore, the pupal inhibition effect was associated with translation inhibition that was overridden by treatment of glands with a cAMP analog, indicating that physical coupling between the PTTH receptor and a protein acting early in the transductory cascade was disrupted by such drugs (Rybczynski and Gilbert, unpublished data). The reason for the larval–pupal difference in microtubule effects on ecdysteroid synthesis is unknown. Note that neither study (Watson *et al.*, 1996; Rybczynski and Gilbert, unpublished data) explicitly monitored the effects of the microtubule disrupting drugs on cytoskeletal structures or cell shape. Note also that the role of the microtubule cytoskeleton in vertebrate steroidogenic cells is not clear. Basal steroidogenesis seems to be generally immune to microtubule-acting drugs while peptide hormone-stimulated steroidogenesis is variably inhibited or not, depending on the cell type and drug concentration (see Feuilloley and Vaudry, 1996). In systems where peptide hormone-stimulated steroidogenesis is inhibited, the data suggest that the pharmacological disruption of microtubules disturbs early events in the signal transduction cascade, e.g., receptor–G protein–cyclase interactions (see Feuilloloey and Vaudry, 1996), a hypothesis consistent with the above-mentioned ability of a cAMP analog to override such a disruption.

The identities of other PTTH-stimulated proteins remain unknown. Attempts to use antivertebrate StAR antibodies against *Manduca* prothoracic gland proteins were not interpretable, due to multiple protein cross-reactions, at a range of MWs, in immunoblot analyses (Rybczynski and Gilbert, unpublished data). Note that the predicted molecular weight of the *Drosophila* MLN64/StAR homolog is considerably larger (≈61 kDa) than the vertebrate molecule (≈30 kDa). PTTH-stimulated protein synthesis is not limited to specific proteins but can also be detected in overall rates of translation (Keightley *et al.*, 1990; Rybczynski and Gilbert, 1994; Kulesza *et al.*, 1994). The amount by which PTTH stimulates overall translation above basal appears to vary with the stage, with V_3 glands responding at about six times the rate of V_1 glands (Rybczynski and Gilbert, 1994). The incubation of nonstimulated prothoracic glands with ^{35}S-methionine revealed that the pattern of translated proteins varied among several stages in the fifth larval instar (Lee *et al.*, 1995); how these changes relate to changes in the ecdysteroidogenic capability of the prothoracic gland, or to PTTH signaling, is unknown. Unfortunately, a more detailed developmental analysis of protein synthesis, both basal and PTTH stimulated, by larval and pupal prothoracic glands remains to be done. As mentioned above, phosphorylation of ribosomal protein S6 preferentially increases the translation of mRNAs containing a 5′-polypyrimidine tract. The identification of these RNAs is undoubtedly incomplete but recent evidence reveals that in vertebrate cells many such RNAs code for ribosomal proteins (see Pearson and Thomas, 1995), suggesting that some of the unidentified PTTH-dependent translation products are also components of the ribosome.

PTTH stimulates transcription in prothoracic glands, based on the incorporation of radiolabeled uridine into acid-precipitable RNA in response to dibutyryl cAMP (Keightley *et al.*, 1990). Inhibition of transcription using actinomycin D resulted in a partial inhibition of both PTTH- and dibutyryl cAMP-stimulated ecdysteroid synthesis (Keightley *et al.*, 1990; Rybczynski and Gilbert, 1995b). These data suggested that transcription may be necessary for a maximal ecdysteroidogenic response to PTTH. However, actinomycin D had a larger effect on translation (≈50% inhibition in a 45-min incubation) than might be expected unless an unprecedented fraction of prothoracic gland proteins was translated from mRNAs with very short half-lives (Rybczynski and Gilbert, 1995b). In other words, the possibility that actinomycin D interfered with translation, as well as with transcription, cannot be ruled out, thus making it difficult to determine the role of transcription in acute increases of ecdysteroidogenesis.

cDNA clones for *Manduca* β1 tubulin and hsc 70 were obtained, with the hope that the expression pattern of these two genes might shed some light on their functions in PTTH signaling. In the prothoracic gland, β1 tubulin mRNA exhibited a peak in the fifth instar just before wandering (Rybczynski and Gilbert, 1998). β tubulin protein levels paralleled the mRNA profile during the fifth instar but in contrast to the mRNA profile, β tubulin protein abundance exhibited a second peak on day 2 (P_2) of pupal–adult development. These data might indicate that β tubulin protein levels are important to glands that are preparing to synthesize large amounts of ecdysteroids but do little to explain

the very rapid synthesis that occurs upon PTTH stimulation (Rybczynski and Gilbert, 1995b). Hsc 70 mRNA levels also showed a peak in the fifth instar, just before wandering (V_4), with lesser peaks on V_7 and P_2 (Rybczynski and Gilbert, 2000). Hsc 70 protein levels showed peaks on V_3, V_7, and P_0 levels, yielding a pattern of expression that does not clearly relate to either prothoracic gland growth or ecdysteroid synthesis. Although the profiles of β tubulin and hsc 70 mRNAs and proteins did not lend themselves to understanding the roles these gene products play in PTTH-stimulated ecdysteroid synthesis, analyses of brain and fat body indicated that the expression patterns of these products were tissue specific (Rybczynski and Gilbert, 1998, 2000). Complicating the question of determining what special roles β tubulin and hsc 70 might play in PTTH signaling in the prothoracic gland is the fact that both these proteins are very abundant and participate in various housekeeping duties in the cell. Discerning a PTTH-specific function against this background is difficult. Clearly, the topic of transcription in PTTH-stimulated ecdysteroid synthesis has not been exhausted and is worthy of further scrutiny.

3.2.4.6. Protein Phosphatases

The stimulation of ecdysteroidogenesis *in vivo* by PTTH is transient, and with varying biosynthetic rates, depending on the developmental stage. Given that PTTH stimulates the phosphorylation of a number of kinases and an unknown number of target proteins, it is reasonable to assume that downregulation of PTTH-stimulated ecdysteroid synthesis involves the activity of protein phosphatases. This topic has received scant attention in regard to the action of PTTH. Song and Gilbert (1996) used okadaic acid and calyculin, highly effective inhibitors of the serine/threonine-specific protein phosphatases 1 and 2A, to address this topic. They found that treatment of *Manduca* prothoracic glands with either of these inhibitors enhanced the phosphorylation of S6, and of several unidentified proteins, but that PTTH-stimulated phosphorylation of S6 was not augmented by a cotreatment with the PP inhibitors. However, although okadaic acid and calyculin increased S6 phosphorylation, these drugs inhibited both basal and PTTH-stimulated ecdysteroid and protein synthesis; included in the latter effect was the apparent inhibition of the syntheses of both β tubulin and hsc 70. Finally, Song and Gilbert (1996) found that PTTH stimulated phosphatase activity capable of dephosphorylating S6, and perhaps other proteins, and that this activity was inhibited by okadaic acid, implicating PP1 and/or PP2A in the downregulation of PTTH effects. The combined data indicated that the multiple phosphorylation of S6, by itself, was not sufficient to drive increased ecdysteroidogenesis. They also suggested that the nonphosphorylated state of one or more proteins was necessary for normal ecdysteroid synthesis, assuming that neither okadaic acid nor calyculin had effects on proteins other than phosphatases. That PTTH both stimulated S6 phosphorylation and dephosphorylation processes were expected given the likelihood that negative feedback loops exist in the prothoracic gland to restore its ecdysteroidogenic activity to basal levels.

The MAP kinases, like the ERK activated by PTTH stimulation (see Section 3.2.4.3), can be dephosphorylated by a number of phosphatases (see Camps *et al*., 2000). Dephosphorylation of ERKs at either the threonine or tyrosine sites results in loss of ERK kinase activity; PP2A and several tyrosine phosphatases, e.g., PTP-SL, STEP, and HePTP, have all been shown to inactivate vertebrate ERKs (see Camps *et al*., 2000). In addition, ERKs and other MAP kinases are dephosphorylated by unique dual-specificity phosphatases (DSPs) that remove phosphates from both threonine and tyrosine residues. These DSPs are probably the major agents of vertebrate ERK inactivation (see Camps *et al*., 2000). Mammals express at least 9 DSP genes and at least one homolog is found in *Drosophila* (D-mkp) (Cornelius and Engel, 1995). Currently, the contributions of various protein phosphatases to the regulation of prothoracic gland ERK phosphorylation are unknown. Serine/threonine phosphatases are likely regulators of proteins, like MEK, that are upstream from ERK and their role can be assessed, in part, by using well-characterized inhibitors like okadaic acid. Understanding the role of DSPs is more difficult and will require, *inter alia*, the further characterization of DSP-specific inhibitors that are currently under development (Vogt *et al*., 2003).

3.2.5. The Prothoracic Gland

The summary view of the PTTH signaling system presented in **Figure 7** is no doubt incomplete and will be subject to future additions and amendments. Among the factors deliberately left out of this scheme are those that cause changes in the prothoracic gland that are either independent of PTTH or that are PTTH dependent but not linked to the rapid regulation of ecdysteroidogenesis. In this section, an overview of these factors, both demonstrated and hypothesized, is presented.

3.2.5.1. Developmental Changes in the Prothoracic Gland

Current evidence indicates that the cells of the prothoracic gland either do not divide after embryonic life or do so very infrequently (see discussion in Rybczynski and Gilbert, 2000). Nevertheless, the gland is far from being a static tissue. A number of components in the PTTH transduction cascade change as the fifth larval instar progresses, as discussed in the previous section. These include an increase in cAMP phosphodiesterase activity, decrease in the ERK phosphorylation response, an increase in the amount of the regulatory subunit of PKA, and a change in calmodulin sensitivity, rendering pupal adenylate cyclase less responsive than the larval enzyme. In addition to these events, a number of additional developmental differences have been described. First, while cell number is constant, cell size changes dynamically and rapidly, accompanied by a number of structural changes. In *Manduca* and *Spodoptera*, cell size, i.e., diameter, is roughly correlated with ecdysteroidogenic capacity during the last larval instar, with large-celled glands being the most productive (Sedlak *et al*., 1983; Zimowska *et al*., 1985; Hanton *et al*., 1993). As expected, as cell size increases, the protein content of the gland also increases. In *Manduca*, total extractable and particulate protein increases from a minimum at the beginning of the fifth instar of ≈3 μg/gland to ±20 μg/gland on V_4; protein levels stay high through V_7 before reaching a low of 10–12 μg/gland on P_0 (Smith and Pasquarello, 1989; Meller *et al*., 1990; Rybczynski and Gilbert, 1995b). Protein content rises again through at least P_4 (Rybczynski and Gilbert, 1995b). Though size matters, the ecdysteroidogenic potential of prothoracic glands is not a simple function of cell size or protein content. An analysis of protein content and ecdysteroidogenesis in V_1 to V_3 *Manduca* fifth instar prothoracic glands revealed that basal and PTTH-stimulated synthesis per milligram of protein increased during this period; that is, ecdysteroid synthesis per gland increased faster than did the gland's total protein content (Rybczynski and Gilbert, 1994). A reanalysis of data gathered throughout the fifth instar of *Manduca* (provided by Smith and Pasquarello, 1989) confirms this observation, and revealed that a peak of basal ecdysteroid synthesis per unit protein occurred on V_4. Levels after V_4 declined but never reached the low seen on V_1. PTTH-stimulated synthesis per milligram of protein exhibited a different pattern. A peak was again seen on V_4 but levels were high and relatively similar from V_2 through V_7, followed by a dip on V_8 and V_9, and then a sharp rise to near V_4 levels on P_0. Note that PTTH-stimulated synthesis per milligram of protein was essentially the same on V_2 and V_3 using the data from Smith and Pasquarello (1989), while Rybczynski and Gilbert (1994) found V_2 levels to be considerably lower than V_3 levels.

An additional developmental change in prothoracic glands has been described for *Bombyx*. *Bombyx* prothoracic glands from the early fifth instar do not respond to PTTH stimulation with either increased ecdysteroid or cAMP synthesis, and are also distinguished by an exceedingly low basal level of steroid synthesis *in vitro* (Sakurai, 1983; Gu *et al*., 1996). However, these glands apparently respond with increased ecdysteroid synthesis to dibutyryl cAMP, suggesting that there is an upstream developmental "lesion" in one or more components of the PTTH signaling pathway (Gu *et al*., 1996, 1997). In contrast, Takaki and Sakurai (2003) found that dibutyryl cAMP did not elicit ecdysteroid synthesis in early fifth instar glands. The reason for the discrepancy in results is not known but might lie in methodological or strain-specific differences among the studies. Further work indicated that early fifth instar glands from *Bombyx* possess an adenylate cyclase that is much less responsive to Ca^{2+}/calmodulin stimulation than that characterized later in the instar when the gland is responsive to PTTH (Chen *et al*., 2001). It is not known if this cyclase difference is sufficient to explain fully the refractory nature of early fifth instar glands, nor is it known what underlies the cyclase behavior, i.e., are different adenylate cyclases present at different developmental stages? The larger question – why are *Bombyx* glands refractory while *Manduca* glands are not – is conjectural. The possibility that the *Bombyx* condition is a consequence of its domestication cannot be excluded.

These observations showing developmental changes in the signaling and biosynthetic components of the prothoracic gland raise an obvious question. What factor(s) controls the growth and differentiation state of the gland? At present, we can only speculate. PTTH is, of course, a candidate. Functionally homologous vertebrate peptide hormones, acting alone or in concert with other factors, often have a differentiation and mitogenic effect on their target tissues in addition to their steroidogenic activity (see Adashi, 1994; Richards, 1994; Richards *et al*., 2002). Presently, two lines of evidence suggest that PTTH may have nonecdysteroidogenic effects on the prothoracic gland. First, PTTH hemolymph titers in *Bombyx* showed a pattern not completely consonant with ecdysteroidogenesis, indicating other roles for this peptide

hormone (see Section 3.2.3.4). Second, PTTH stimulates two categories of protein synthesis in the *Manduca* prothoracic gland (Rybczynski and Gilbert, 1994). One class of proteins comprised a small group of molecules whose translation appears to be linked to PTTH-stimulated ecdysteroidogenesis and presumably includes one or more proteins that are necessary for PTTH-stimulated increases in steroid synthesis (see also Song and Gilbert, 1995). The second class of translation products was less well defined and might include most, if not all, house-keeping mRNAs in the prothoracic gland. Translation of this group of proteins was detected by increases in the acid-precipitable, radiolabeled proteins and not by particular pattern changes discernible in protein bands following SDS-PAGE. This second class of translation products has been considered to reflect a trophic, nonsteroidogenic effect of PTTH (Rybczynski and Gilbert, 1994) and does not appear to be an obligate result of PTTH stimulation of prothoracic glands. For instance, PTTH stimulation of *Manduca* V_1 glands did not measurably increase overall protein synthesis while the increases in translation of specific proteins and in ecdysteroid synthesis were readily seen (Rybczynski and Gilbert, 1994). Furthermore, the Ca^{2+} ionophore A23187 stimulated ecdysteroid and specific protein synthesis in V_2 and V_3 glands but had no effect (V_2) or an inhibitory effect (−50%: V_3) on general, trophic protein synthesis. Simultaneous stimulation with both A23187 and dibutyryl cAMP, admittedly a pharmacologically complex situation, likewise stimulated both ecdysteroid and specific protein synthesis while decreasing general protein synthesis below basal on all 3 days studied (V_1–V_3) (Rybczynski and Gilbert, 1994). Whether the trophic effect of PTTH occurs beyond stages V_2 and V_3 is currently unknown; it would not be surprising if the effect was minimal during periods when the prothoracic gland is not growing appreciably, e.g., V_5 to P_0.

It seems likely that PTTH also stimulates transcription in the prothoracic gland that is not linked to acute regulation of ecdysteroid synthesis. Again, if parallels between vertebrate and insect steroidogenic tissues hold true, it is expected that PTTH stimulation of prothoracic glands would upregulate transcription of mRNAs that code for the enzymes that synthesize ecdysteroids from cholesterol, as well as ancillary, supportive proteins like adrenodoxin reductase (see Simpson and Waterman, 1988; Orme-Johnson, 1990; **Chapter 3.3**). The recent cloning of several of the cytochrome P450s that are involved in ecdysteroid synthesis in *Drosophila* should allow this issue to be addressed in the near future (see **Chapter 3.3**). This transcriptional trophic effect, like that of translation, may be limited to certain developmental periods. A lack of effect would not be surprising in the period immediately preceding prothoracic gland apoptosis in those species where such programmed cell death occurs (see Section 3.2.5.4).

3.2.5.2. Regulators of the Prothoracic Gland other than PTTH

The prothoracic gland, like other internal organs, is bathed in hemolymph and is potentially regulated by any number of the hormones found in the hemolymph, in addition to PTTH. The influence of the juvenile hormones has been discussed (see Section 3.2.3.3; and **Chapters 3.7**, **3.9**, **3.11**, and **3.12**) but it bears repeating that the evidence is weak for direct regulation of prothoracic gland physiology by JHs. Aside from JHs and the ecdysteroids that are covered in Section 3.2.5.3, most, if not all, of these hormones are peptides or small proteins (see **Chapter 3.10**).

Several prothoracicotropic factors, which were partially purified from lepidopteran proctodaea, are discussed briefly in Section 3.2.2.5. Rather more far afield was the observation that an ovarian-derived dipteran oostatic factor (trypsin modulating oostatic factor or TMOF) appears to exert dose-dependent stimulatory and inhibitory effects on ring gland and prothoracic gland basal and PTTH-stimulated ecdysteroid production (Hua and Koolman, 1995; Hua *et al*, 1999; Gelman and Borovsky, 2000). The ecdysiostatic effect of TMOF, a hexapeptide, on *C. vicina* ring glands was attributed to a TMOF-dependent rise in cAMP, with the latter being found to be inhibitory of basal ecdysteroidogenesis (Hua and Koolman, 1995). However, an earlier study showed that dibutyryl cAMP stimulated *Calliphora* ring gland ecdysteroidogenesis (Richard and Saunders, 1987) and it is not currently possible to reconcile these conflicting observations about cAMP. How TMOF might exert a prothoracicotropic effect rather than an ecdysiostatic effect under some conditions is also not known. Thus, these observations are intriguing but the *in vivo* significance of TMOF in regard to prothoracic gland function remains to be rigorously determined.

Another small molecule, a nonapeptide termed prothoracicostatic peptide (PTSP), has been purified from *Bombyx* brain (Hua *et al*., 1999). This peptide, identical in sequence to a myoinhibitory peptide first isolated from *Manduca* ventral nerve cord (Mas-MIP I: Blackburn *et al*., 1995), was able to inhibit basal (Hua *et al*., 1999; Dedos *et al*., 2001) and

PTTH-stimulated (Hua *et al.*, 1999) ecdysteroidogenesis *in vitro* in a dose-dependent manner. PTSP appears to block "basal" Ca^{2+} influx via dihydropyridine-sensitive channels (Dedos *et al.*, 2001; Dedos and Birkenbeil, 2003) but PTSP did not block PTTH-stimulated Ca^{2+} influx (Dedos and Birkenbeil, 2003). It is difficult to reconcile the latter observation with the finding that PTSP blocked PTTH-stimulated ecdysteroid synthesis (Hua *et al.*, 1999), given that PTTH-stimulated ecdysteroid synthesis requires Ca^{2+} influx. Furthermore, rather large doses were required ($\geq$100 nM) to achieve an ecdysteroidogenic inhibition relative to the dose needed for myoinhibition (1 nM; Blackburn *et al.*, 1995). Davis *et al.* (2003), using immunohistochemical techniques, have found that an apparent release of MIP I (PTSP) from *Manduca* epitracheal glands appears to coincide with the rapid drop in ecdysteroid hemolymph titer that occurs just prior to larval ecdysis. This intriguing observation deserves confirmation, e.g., via studies under long-day conditions, where this ecdysteroid decline occurs approximately 24 h before ecdysis, or in the fifth instar, where ecdysteroid levels begin a fall several days before pupal ecdysis (Bollenbacher *et al.*, 1981; Grieneisen *et al.*, 1993). Given these data calling into question the *in vivo* function of this peptide, it seems safest to consider PTSP a candidate prothoracicostatic factor, pending further studies. If PTSP does occur *in vivo* at high nanomolar concentrations, it is likely to have wide effects beyond the prothoracic gland, i.e., many cell types undoubtedly express dihydropyridine-sensitive Ca^{2+} channels the inhibition of which would affect cellular function throughout the organism.

The changing electrical properties of prothoracic glands during diapause were discussed above in regard to *Manduca* PTTH (see Section 3.2.3.6). However, the electrical properties of prothoracic glands may be important in another context, i.e., as a factor in species wherein the prothoracic gland is innervated. Innervation of prothoracic glands is widely distributed among taxa, but it is not clear that it is a universal feature within any given insect group, e.g., the Lepidoptera contain species with and without innervation (see Sedlak, 1985; references in Okajima and Watanabe, 1989). The role of innervation in chronic or acute regulation of ecdysteroid synthesis has not been well studied. In *P. americana*, the activity of a nerve originating from the prothoracic ganglion was correlated positively with the secretion of ecdysteroids from the prothoracic gland (Richter and Gersch, 1983) but experimental discharge of this nerve did not have a significant effect on ecdysteroidogenesis (Richter, 1985). Sectioning the prothoracic gland nerve of last instar larvae prevented the normal ecdysteroid peak seen between days 20 and 24 but the subsequent larger peak seen after day 26 was unaffected. These observations suggest a bimodal control of *Periplaneta* ecdysteroid synthesis in this instar, with the second peak presumed to be controlled solely by PTTH. However, a role for PTTH in the first peak cannot be ruled out, i.e., neuronal input could control the reactive state of the gland, in regard to PTTH, without directly regulating ecdysteroidogenesis.

In the moth *Mamestra*, the neurons innervating the prothoracic gland are inhibitory in regard to basal ecdysteroid synthesis but their effect on PTTH-stimulated synthesis is not known (Okajima and Watanabe, 1989; Okajima and Kumagai, 1989; Okajima *et al.*, 1989). Conflicting data on the role of innervation complicates any attempt to generalize at this time. For instance, Alexander (1970) proposed an inhibitory role in *Galleria* for the prothoracic gland nerve originating in the subesophageal ganglion while Mala and Sehnal (1978) argued for an excitatory (steroidogenic) influence. Neuronal input to the prothoracic gland may also originate in the brain. In both *S. crassipalpis* and *Drosophila*, species possessing the compound endocrine structure termed the ring gland, histochemical studies using back-filling techniques and reporter genes revealed that cells of the lateral protocerebrum directly innervate the ring gland (Giebultowicz and Denlinger, 1985; Siegmund and Korge, 2001). In the case of *Drosophila*, the identified cells appear to be neurosecretory, based on size and distinctive morphology. In *Sarcophaga*, several of these cells, presumably also neurosecretory, terminated in the corpus allatum region of the ring gland, as found for the PTTH-producing cells of lepidopterans. *Drosophila*, like *Sarcophaga*, contained several cells in the lateral protocerebrum that innervated the corpus allatum region. However, *Drosophila* also contained a pair of cells that innervated the prothoracic gland region of the ring gland. This observation suggests that if the neuronal cells in question regulate ecdysteroid synthesis, such regulation may not proceed as in the Lepidoptera, i.e., a soluble PTTH, released into the general circulation, might not be needed. In fact, a *Drosophila* PTTH with homology to the lepidopteran molecules might be completely lacking and its function taken over by another signaling molecule, perhaps even one that is considered a conventional neurotransmitter.

Clearly, the part that prothoracic gland innervation plays in affecting steroid synthesis deserves further attention. At present, based on structural studies, it seems likely that direct nervous input

from ganglia is primarily via peptides rather than neurotransmitters (see Sedlak, 1985). Peptidergic input may reflect a chronic or modulatory role for neuronal input in the control of prothoracic gland function; the possibility that such peptides may serve as trophic factors important for gland survival as seen for vertebrate nerve growth factor (see Levi-Montalcini *et al.*, 1996) is an intriguing and unexplored topic.

The changes in prothoracic gland cell size, protein content, and ecdysteroidogenic potential that have been documented during larval and pupal–adult development may be influenced heavily by the trophic influences of PTTH and, in some species, neurotrophic factors, as discussed above. Additional strong candidates for the regulation of prothoracic gland biology during development are the insect insulin-like proteins (ILPs). As discussed earlier (see Section 3.2.2.5), insects have a number of such genes (seven in *Drosophila*; Brogiolo *et al.*, 2001) and at least four lines of evidence suggest that one or more ILPs might affect prothoracic gland biology. First, it has been known for decades that insulin is helpful or even necessary for the growth (division) of some insect cells in culture (Mosna and Barigozzi, 1975; Davis and Shearn, 1977). Second, the cells of the prothoracic gland undergo large changes in size during development and the insect insulin pathway is involved in regulating cell size, not only cell cycling. For instance, a mutation in the *Drosophila* insulin receptor substrate gene *Chico* yields flies that are small because their cells are small (see Goberdhan and Wilson, 2003). Third, antibody studies suggest that the prothoracic gland expresses an insulin receptor (Smith *et al.*, 1997; see also Section 3.2.4.3). Fourth, there is precedence for insulin control of ecdysteroid synthesis, although in the mosquito ovary and not the prothoracic gland (Graf *et al.*, 1997; Riehle and Brown, 1999). The idea that insulin affects prothoracic glands in some way must be tested rigorously. Especially useful will be the presumed future availability of authentic insect insulin-like molecules, their use in well-characterized *in vitro* experimental regimes, and the determination of the titers of insulin-like proteins in the hemolymph during larval and pupal–adult development.

3.2.5.3. Ecdysteroid Feedback on Ecdysteroidogenesis in the Prothoracic Gland

The rise and fall of circulating hormone levels is characteristic of many endocrine signaling events, including the coordination of larval and pupal–adult development of insects by ecdysteroids (see **Chapter 3.8**). Several processes contribute to the regulation of circulating levels of active hormone, e.g., secretion rates, metabolism to inactive forms, sequestration, and excretion. The secretion rate is itself the product of multiple variables, namely: substrate availability, maximum biochemical synthesis rates, stimulation of the producing tissue by a trophic factor, product storage, presence of inhibitory factors, product feedback, etc.

Ecdysteroid feedback on the prothoracic gland, both positive and negative, can proceed through at least two paths. First, ecdysteroids might directly interact with the prothoracic gland, potentially resulting in rapid or slow changes in the PTTH signaling cascade or the ecdysteroid biosynthetic pathway. Second, ecdysteroids might act indirectly, by modifying the behavior of another tissue, which then, through a nonecdysteroid pathway, modulates the biology of the prothoracic gland.

Only a limited amount of data has been gathered to test the hypothesis that the prothoracic gland is subject to both rapid and delayed feedback from ecdysteroids. Sakurai and Williams (1989) showed that incubating larval *Manduca* prothoracic glands for 24 h with low concentrations of 20E (e.g., 0.20 μM) resulted in an inhibition of 20% to 60% of basal ecdysteroid synthesis. In contrast, pupal glands generally experienced a stimulation of synthesis. This was true of prothoracic glands from both nondiapausing and diapausing pupae but the effect of PTTH on these glands was not evaluated. A study of the effect of shorter 20E incubations on basal and PTTH-stimulated *Manduca* glands revealed that when a higher dose (10 μM) of 20E was employed a very significant inhibition of basal ecdysteroidogenesis (≈75%) was seen after only 1 h of incubation (Song and Gilbert, 1998); note that in these experiments, prothoracic glands were preincubated with exogenous 20E but their ecdysteroid production was measured subsequently in medium lacking the supplemental 20E. Somewhat surprisingly, this regime of pretreatment with 20E had no effect on PTTH-stimulated ecdysteroid synthesis, relative to controls not incubated with 10 μM 20E, unless the preincubation was for more than 3 h. These observations suggest that the repression of basal ecdysteroid synthesis after short incubations was due to a reversible block in the steroidogenic pathway that could be overcome by PTTH stimulation. What constitutes this block is open to speculation. The data currently in hand suggest that the PTTH signal transduction pathway is not measurably active in regulating steroidogenesis in the absence of PTTH. Perhaps the rapid 20E effect on basal steroidogenesis was due to direct, competitive inhibition by 20E of some step in ecdysteroid

synthesis. This possibility could be tested by using lower concentrations of 20E and non-steroidal compounds that bind to the ecdysone receptor but that would not be expected to interact with the biosynthetic enzymes involved in ecdysteroidogenesis (see **Chapters 3.3** and **3.4**). In fact, Jiang and Koolman (1999) used the non-steroidal ecdysone agonist RH-5849 in such a test, using *C. vicina* ring glands. Their results revealed that RH-5849 inhibited basal ecdysone secretion rapidly, with more than 50% inhibition seen within 30 min of incubation. These data suggest that ecdysteroid feedback on the prothoracic gland involved regulation of transcription or nongenomic effects, perhaps mediated through second messenger signaling initiated via a plasma membrane ecdysteroid receptor (see **Chapter 3.7**). How such signaling might interact with the basal synthesis pathway is unknown; it is possible that RH-5849 interferes with the synthesis pathway in a manner unrelated to its ecdysone agonist effect.

Longer incubations (>3 h) with 20E, resulted in the downregulation of steroidogenesis which was not fully reversible with PTTH (brain extract) treatment (Song and Gilbert, 1998). This effect seems likely to be due to changes in transcription and translation, and this hypothesis should be testable using newly, or soon-to-be, available molecular probes against the transcripts coding for the ecdysteroidogenic enzymes (see **Chapter 3.3**). Incubation of *Manduca* prothoracic glands with 10 μM 20E altered the expression pattern of USP proteins within 6 h (Song and Gilbert, 1998). USP is an obligate partner to the EcR protein in forming the functional ecdysteroid receptor (see **Chapter 3.5**), and this change might be a sign of an altered transcription pattern in the gland. The possibility that components of the PTTH signaling pathway were also downregulated cannot be ruled out and this supposition could also be tested using molecular probes, or by using commercially available antibodies to assess protein levels and the phosphorylation states thereof.

The above data suggested that 20E levels directly regulated basal and PTTH-stimulated ecdysteroid synthesis by the prothoracic gland. An indirect type of 20E feedback on prothoracic gland activity, involving one or more intermediate tissues, is also a possibility. In *Bombyx*, early fifth instar glands are refractory to PTTH stimulation *in vitro* (see Sections 3.2.3.3 and 3.2.5.1; and see **Chapter 3.8**). Injection of 0.5–4.0 μg 20E into intact *Bombyx* larvae also resulted in partial inhibition of basal ecdysteroid synthesis at the higher doses, when glands from treated animals were later assayed *in vitro* (Takaki and Sakurai, 2003), but a consistent effect of 20E injection on PTTH-stimulated ecdysteroid synthesis was not seen. However, when the brain and corpora allata were removed from larvae prior to control (water) or 20E injections, somewhat different results were obtained. First, at stages where basal ecdysteroid synthesis was expected to have declined between the treatment and sampling periods in response to exogenous 20E, such declines were absent or blunted. Second, when such glands were challenged with PTTH, the gland activation was larger than expected. These results suggested that 20E might downregulate prothoracic gland activity via stimulating the release of an inhibitory brain or corpus allatum factor (see Section 3.2.5.2). Whether or not both direct and indirect feedback of 20E on prothoracic glands occurs in nonmanipulated animals is an open question. The effects seen upon removal of the brain and corpora allata are suggestive, but this operation removes a Pandora's box of cell types, neuronal connections, and hormones, and the results stemming from such an operation must be interpreted with care.

3.2.5.4. Apoptosis of the Prothoracic Gland

Programmed cell death or apoptosis is a normal component of development in multicellular organisms, including insects, and involves a complex, multistep cascade of intracellular events (see Vernooy *et al*., 2000). The only demonstrated function of the prothoracic glands is to produce ecdysteroids and thus to control and coordinate the molting process. It is not surprising, therefore, that prothoracic glands undergo apoptosis during pupal–adult development or early in adult life, once sufficient ecdysteroids have been produced to accomplish this last molt. Programmed cell death of the prothoracic glands occurs in insects that possess a structurally distinct gland, like Lepidoptera, as well as in species possessing a ring gland, where the prothoracic gland is part of a composite, multi-tissue organ.

In *Drosophila*, the degeneration of the prothoracic gland portion of the ring gland during pupal–adult development takes place at a time when whole animal ecdysteroid titers are high and production of ecdysteroids *in vitro* is low (Dai and Gilbert, 1991). This observation led to the suggestion that the source of ecdysteroids at this time was either another tissue, e.g., oenocytes, or the conversion of previously produced hormone from a inactive, conjugate to an active form, with the conjugate not being recognized by the radioimmunoassay employed to assess steroid hormone levels (Dai and Gilbert, 1991). Given the uncertainties about

the control of ecdysteroid synthesis in *Drosophila* discussed earlier in this chapter, it is also possible that the production *in vitro* is not an accurate index of steroidogenesis *in vivo*; however, this hypothesis presupposes that a prothoracic gland that is undergoing apoptosis is still capable of considerable ecdysteroid synthesis.

The structural and hormonal correlates of the programmed cell death of the *Manduca* prothoracic gland, a "free-standing" tissue, have been addressed by Dai and Gilbert (1997, 1998, 1999). In this species, apoptosis of the gland was initiated on day 6 (P_6) of pupal–adult development (Dai and Gilbert, 1997). P_6 is approximately 2 days after the pupal–adult peak of ecdysteroidogenesis and is a time when fat body and hemocytes begin to envelop the gland (Dai and Gilbert, 1997). Ecdysteroid synthesis fell rapidly after P_6, as the glands continued to degenerate, and by P_{14}, only cellular debris was present.

The external factors controlling apoptosis of the prothoracic gland have been partially determined. The absence of juvenile hormones at the beginning of pupal–adult development was originally believed to be an enabling condition (Wigglesworth, 1955; Gilbert, 1962) and subsequent data supported this proposal, i.e., injection of JH into pupae at this stage prevented gland death (Gilbert, 1962; Dai and Gilbert, 1997). The absence of JH was not sufficient to initiate apoptosis because prothoracic glands extirpated from early pupal stages and placed in JH-free culture conditions do not undergo apoptosis (Dai and Gilbert, 1999). Nevertheless, a hormonal basis for gland apoptosis was indicated because the addition of 20E to these cultures efficiently promoted programmed cell death, if the steroid exposure was $\geq$24 h. The 20E doses found to be effective *in vitro* were well within the physiological range seen in the days preceding normal, *in vivo* cell death. These cultured-gland experiments also revealed an extra level of complexity in the control of prothoracic gland apoptosis, namely, that JH did not protect glands *in vitro* against 20E-induced cell death (Dai and Gilbert, 1999). Thus, once again, the role of JHs in modulating prothoracic gland physiology was indirect, involving another tissue and probably another hormone. One might also conclude that 20E-induced apoptosis of the prothoracic gland represents the ultimate negative feedback loop for this steroid hormone-producing gland.

3.2.5.5. Parasitoids and Ecdysteroidogenesis

Insect parasitoids lay their eggs on or in host insects. Following hatching, the parasitoid develops until finally emerging, with the host generally dying as a result of the infection. Parasitoids manipulate the physiology of the host organism to their advantage and this often includes disrupting the normal function of the host's endocrine system (see Beckage, 1985, 1997, 2002). It must also be pointed out that parasitoid infections are biologically complex, involving not only the parasitoid, but also ovarian proteins, symbiotic viruses, and venoms. These additional factors can have major effects on the host's physiology, even in the absence of the parasitoids.

Parasitoids utilize a wide variety of tactics to increase the suitability of their hosts as growth chambers and even a modest review of the subject is beyond the constraints of this chapter (see Beckage, 1985, 1997, 2002). However, several endocrine effects are frequent enough to deserve mention in the context of considering PTTH. One of the most common effects of parasitoid infestation appears to be elevated JH levels. These high titers result in developmental arrest of the host and stem from multiple factors, including increased secretion by the host, decreased degradation, and JH secretion by the parasitoid and perhaps by parasitoid-derived teratocytes (Cole *et al.*, 2002). Elevated levels of JH may act partly through blocking PTTH release since increased levels of PTTH in brains of parasitized *Manduca* have been observed (Žitňan *et al.*, 1995). In some Lepidoptera–parasitoid interactions, the prothoracic gland disintegrates, e.g., *H. virescens* parasitized by *Campoletis sonorensis*, an ichneumonid wasp (Dover and Vinson, 1990; Dover *et al.*, 1995), while in other species, the gland persists. In prothoracic glands from *Manduca* parasitized by *Cotesia congregata*, a braconid wasp, both basal and brain extract-stimulated ecdysteroid synthesis *in vitro* were lower than synthesis from glands of nonparasitized larvae (Kelly *et al.*, 1998). This is strongly reminiscent of the effect of experimentally augmented JH levels on prothoracic glands discussed in Section 3.2.3.3, and is consistent with a view that this parasitism interaction, which blocks development in the fifth instar, is essentially a juvenalizing event. Evidence from *in vitro* studies suggested that a portion of the elevated JH in this example was secreted by the parasitoid and did not simply result from decreased JH catabolism (Cole *et al.*, 2002). *In vivo* ecdysteroid levels at this time were not strongly suppressed relative to control early fifth instar larvae, but the high premolt peak seen normally in the second half of the fifth instar was absent. Ligation experiments revealed that it was likely that some ecdysteroids were secreted by the parasitoid *Cotesia* (Gelman *et al.*, 1998). A stronger suppression of ecdysteroid hemolymph titer has been described for precocious prepupae of

Trichoplusia ni parasitized by the wasp *Chelonus* near *curvimaculatus* (Jones *et al*., 1992); in this interaction, an ecdysteroid peak observed shortly before the emergence of the parasitoid larvae was also believed to originate with the parasitoid.

Evidence that parasitism has a direct effect on the functioning of the prothoracic gland comes primarily from work on *H. virescens* parasitized by the braconid wasp *Cardiochiles nigriceps*. In this interaction, basal ecdysteroid synthesis by the glands was considerably depressed when measured *in vitro* (Pennacchio *et al*., 1997, 1998a); JH levels were elevated and JH metabolism depressed in parasitized larvae during the first 4 days of the final larval instar (Li *et al*., 2003). Such glands showed no activation when challenged with a crude PTTH extract or forskolin (an adenylate cyclase activator) or dibutyryl cAMP; but all three reagents stimulated ecdysteroid synthesis in control glands. Further investigation revealed several biochemical lesions downstream from cAMP generation (Pennacchio *et al*., 1997, 1998a), including depressed basal protein synthesis and phosphorylation and a failure to increase protein phosphorylation and synthesis upon PTTH stimulation. No difference in RNA synthesis was found between control and parasite-derived glands (Pennacchio *et al*., 1998a). Surprisingly, the effects of *Cardiochiles* parasitism on the prothoracic gland proved to be largely the result of coinfection with the *C. nigriceps* polydnavirus that is injected into the host along with the *Cardiochiles* eggs and venom (Pennacchio *et al*., 1998b). Venoms also play a role in parasitoid manipulation of host prothoracic glands. The venom of the ectoparasitic wasp *Eulophus pennicornis*, when injected into larvae of the tomato moth (*Lacanobia oleraceae*) results in depressed basal ecdysteroid synthesis by prothoracic glands when assayed 48 h later and, furthermore, such glands failed to respond to forskolin with increased steroidogenesis (Marris *et al*., 2001). However, incubation of prothoracic glands with venom extract for 3 h had no effect. This observation suggests that either venom requires a longer time to disrupt the PTTH transduction cascade, or that an intermediate tissue is involved in the venom effect.

These and similar observations suggest that the roles of viruses and venoms in manipulating host endocrine systems can be great. How parasitoids and their coevolved, symbiotic viruses influence the PTTH-prothoracic gland axes of their hosts is far from resolved and might well involve a number of tactics that include altering hormone synthesis and prohormone conversion by their hosts (Beckage, 1985), hormone release, and feedback systems.

3.2.6. PTTH: The Future

At the end of a review article, it is both a cliché and a truism to write phrases like "While we have learned a great deal about this topic in the last few years, there is clearly much left to be understood," and "Although we have obtained the answers to many questions about this topic, the answers have raised even more questions." These comments are certainly true about PTTH, and many unanswered and new questions about PTTH have been raised in this review. Finally, a few of these questions will be iterated and a few new ones added. The answers to these questions will require not only new methodologies and model systems, but also new ways of looking at familiar topics.

What we know about PTTHs derives chiefly from studies of Lepidoptera. Are there closely related molecules in all or most other taxa, or do other pathways function, e.g., total neuronal control of ecdysteroid synthesis? Similarly, our knowledge of PTTH signaling within the prothoracic gland comes almost entirely from lepidopteran studies. Are other, significantly different control mechanisms used? Certainly, the work on putative PTTH-containing extracts from *Drosophila* suggests that the control of ecdysteroid synthesis by hormones originating outside the prothoracic gland might proceed by novel means.

Even within the scope of lepidopteran studies, a great deal of the control pathway activated by PTTH remains to be determined. We have little knowledge of negative feedback mechanisms, and the function of the developmental changes seen in prepupal prothoracic glands is currently mainly a source of speculation. The necessity for new protein synthesis in PTTH-stimulated ecdysteroidogenesis is well established but the role of such protein(s) has not been determined. If one of these proteins facilitates steroid precursor movement, as in vertebrate steroidogenesis, what do the other proteins do? Another question concerns the complexity of PTTH signal transduction (see **Figure 7**). If the prothoracic gland's only function is to make ecdysteroids, why is the PTTH signaling cascade, which we know imperfectly, so complex? Are the multiple kinase networks simply cellular fossils that reflect a lack of selection to simplify, with layer upon layer of control mechanisms, as evolution sharpened the control of steroid synthesis?

If there might be proposed one final "big" question about PTTH, perhaps the best candidate would be "What else does PTTH do?" *Bombyx* PTTH was first purified from the heads of adult animals, long

after the prothoracic glands have disintegrated via programmed cell death. Is this PTTH reservoir an artifact of the domestication of *Bombyx*, or does PTTH modulate the physiology of other cell types, steroidogenic or not?

Insects comprise a very large fraction of the animal world with which mankind must coexist and compete with for the world's resources. We can only hope that the human resources to study these questions keep pace with our need to understand and adapt to this amazing class of animals.

3.3 Ecdysteroid Chemistry and Biochemistry

R Lafont and C Dauphin-Villemant, Universite Pierre et Marie Curie, Paris, France
J T Warren, University of North Carolina, Chapel Hill, NC, USA
H Rees, University of Liverpool, UK

3.3.1. Introduction

It is not the aim here, owing to the limitations of space, to review all the literature concerning the chemistry and biochemistry of ecdysteroids, and the reader should consult older articles in several excellent reviews by Denis Horn (Horn, 1971; Horn and Bergamasco, 1985) and the book edited by Jan Koolman (Koolman, 1989). After a short historical introduction, we will focus on recent data concerning (1) the techniques used for ecdysteroid analysis and (2) the biosynthesis and metabolism of these hormones. However, we will not give details about chemical synthesis procedures, and we will limit this topic to a few chemical reactions that can be performed by (trained) biologists and do not require an experienced chemist.

The endocrine control of insect molting was established in part by the pioneering work of Stefan Kopec (1922), who demonstrated the need for a diffusible factor originating from the brain (see **Chapter 3.2**) in order for metamorphosis to take place in the gypsy moth, *Lymantria dispar*. This role of the brain was further substantiated by Wigglesworth (1934) with experiments using the blood-sucking bug *Rhodnius prolixus* to define "critical periods" for the necessity of the brain to produce a molting factor (see **Chapter 3.2**). The presence in the hemolymph of a molting/metamorphosis hormone was also established by other approaches: Frew (1928) cultivated imaginal discs *in vitro* in hemolymph from either larvae or pupae and he observed their evagination in the second medium only; Koller (1929) and Von Buddenbrock (1931) observed that the injection of hemolymph of molting animals into younger ones was able to accelerate molting of the latter. Fraenkel (1935) ligated larvae of *Calliphora erythrocephala* and observed pupation in the anterior part only; this provided a basis for the establishment of a bioassay for molting hormone activity, later used for the isolation of ecdysone (E) by Butenandt and Karlson (1954). The use of double ligation experiments with *Bombyx mori* larvae allowed Fukuda (1940) to demonstrate that a factor originating in the brain (i.e., the "brain hormone") (see **Chapter 3.2**) was relayed to an endocrine gland situated in the prothorax that produced the true "molting hormone." This

prothoracic gland was first described by Ke (1930); it is termed "ventral gland" in locusts, and in Diptera it is part of a complex endocrine structure, the "ring gland." In fact, the direct demonstration that prothoracic glands indeed produce E came much later (Chino *et al.*, 1974; King *et al.*, 1974; Borst and Engelmann, 1974), by the analysis of the secretory products of prothoracic glands cultivated *in vitro*. One year later, Hagedorn *et al.* (1975) demonstrated that the ovary of adult mosquitoes was another source of E, and this was the basis for establishing the role of ecdysteroids in the control of reproduction.

The first attempts to purify the molting hormone were performed by Becker and Plagge (1939) using the *Calliphora* bioassay derived from Fraenkel's work. α-Ecdysone was isolated in 1954 by Butenandt and Karlson after 10 years of attempts to do so. These authors used *B. mori* pupae because this material was available in large amounts. Ten more years of work was necessary to elucidate E's structure, which was finally achieved using X-ray crystallography analysis (Huber and Hoppe, 1965). A detailed description of this story can be found in Karlson and Sekeris (1966), and it is of great interest to follow how E was progressively characterized and to compare this work with what can be accomplished with presently available tools.

A second molecule, 20-hydroxyecdysone (20E) (initially termed β-ecdysone) was described soon thereafter, and this molecule was also isolated from a crayfish (Hampshire and Horn, 1966). It was rapidly established that 20E was the major molting hormone of all arthropods. Amazingly, E, which was the first of these compounds to be isolated, is at best a minor compound in most insect species when detectable, with the exception of young lepidopteran pupae, i.e., the material used by Butenandt and Karlson. Other closely related molecules were then isolated and the generic term of "ecdysteroids" was proposed for this new steroid family (Goodwin *et al.*, 1978). Meanwhile, ecdysteroids had also been isolated from plants, hence the terms "zooecdysteroids" and "phytoecdysteroids."

3.3.2. Definition, Occurrence, and Diversity

Ecdysteroids could be defined either by their biological activity (molting hormones) or their chemical structure. They represent a specific family of sterol derivatives comprising more than 300 members that bear common structural features: a *cis* (5β-H) junction of rings A and B, a 7-ene-6-one chromophore, and a *trans* (14α-OH or –H) junction of rings C and D (Figure 1). Most of them also bear the 3β-OH already present in their sterol precursor, and a set of other hydroxyl groups located both on the steroid nucleus and the side chain (Figure 2) that renders them rather water soluble. The major insect ecdysteroid is 20E, a 27-carbon (27C) molecule derived from cholesterol (C), but some insect species contain its 28C or 29C homologs, makisterone A and makisterone C, respectively (Figure 3).

The huge chemical diversity of ecdysteroids results from variations in the number and position of –OH groups, which can be either free or conjugated to various polar or apolar moieties, giving rise to the 70 different molecules presently described in insects listed in Table 1 (more information about these molecules can be found on the Ecdybase website). The greatest diversity has been found in the eggs/embryos of Orthoptera and Lepidoptera, probably because they contain very large amounts of these molecules (up to 40 μg g^{-1} fresh weight, i.e., 10 to 100 times the concentrations found in larvae or pupae). The nomenclature of insect ecdysteroids is generally derived from the ecdysone name, but

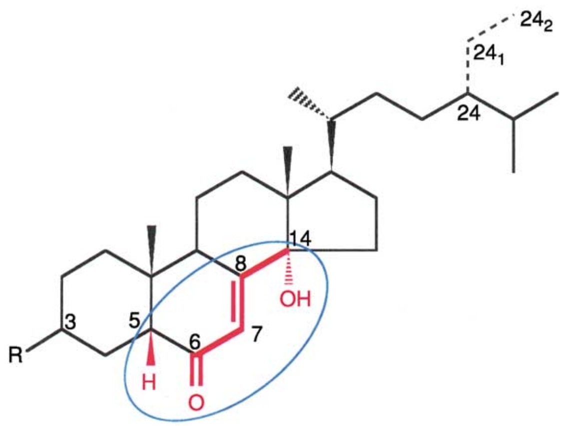

Figure 1 Common structural features of ecdysteroids (major characteristics are indicated in red/blue; R = 3β-OH in most cases).

Figure 2 Space-filling model of the 20-hydroxyecdysone molecule. Blue: carbon atoms; red: oxygen atoms; white: hydrogen atoms. (Courtesy of Pr J.-P. Girault.)

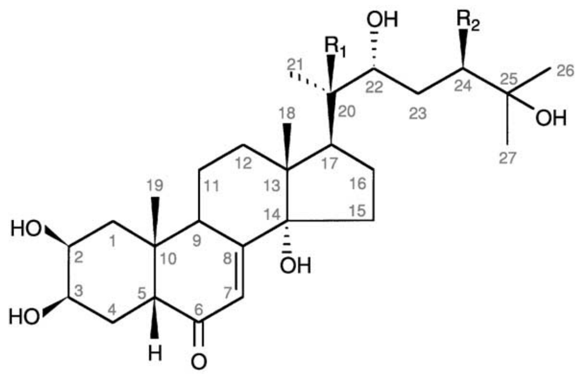

Figure 3 Structures of the major insect ecdysteroids. $R_1 = R_2 = H$: ecdysone (E); $R_1 = OH$, $R_2 = H$: 20-hydroxyecdysone (20E); $R_1 = OH$, $R_2 =$ methyl: makisterone A; $R_1 = OH$, $R_2 =$ ethyl: ethyl: makisterone C.

this is always the case, and the trivial name of many ecdysteroids (especially phytoecdysteroids) is related to the name of the species from which they have been isolated; standardized abbreviations have been proposed for insect ecdysteroids (Lafont *et al.*, 1993a) and are used throughout this chapter.

3.3.3. Methods of Analysis

3.3.3.1. Methods of Identification

3.3.3.1.1. Physicochemical properties
3.3.3.1.1.1. UV spectroscopy The 7-en-6-one group of ecdysteroids has a relatively strong absorption at $\lambda_{max} \sim 243$ nm with an ε of ~ 10–16 000: for instance E, has a λ_{max} at 242 nm and an ε of 12 400 in EtOH. This maximum of absorbance is shifted to 247 nm in water.

3.3.3.1.1.2. IR spectroscopy The presence of a number of hydroxyl groups on most ecdysteroids ensures a strong absorption in the infrared (IR) spectrum in the region of 3340–3500 cm^{-1}. The αβ-unsaturated ketone results in a characteristic cyclohexenone absorption at 1640–1670 cm^{-1}, with a weaker alkene stretch at approximately 1612 cm^{-1}. An additional carbonyl absorption is seen with 3-dehydroecdysteroids: thus 3-dehydroecdysone (3DE) and 3-dehydro-20-hydroxyecdysone (3D20E) show a carbonyl absorption at 1712 cm^{-1} and 1700 cm^{-1}, respectively, in addition to the usual 7-ene-6-one signal. Among conjugates, the absorption of phosphates ranges from 1100 to 1000 cm^{-1}. Acetates and acyl esters can be characterized by additional bands corresponding to the carbonyl and to the ester group. Ecdysteroids are not soluble in the usual infrared solvents (CS_2, CCl_4, $CHCl_3$) so IR spectra are done on KBr discs or mineral oil (Nujol) mulls. The development of Fourier transform spectrometers (FT-IR) allows the solubility problem to be overcome, as dilute solutions can be analyzed. Thus, IR spectra can even be recorded in-line during HPLC analysis (Louden *et al.*, 2001, 2002).

3.3.3.1.1.3. Fluorescence In the presence of sulfuric acid or aqueous ammonia, ecdysteroids are induced to fluoresce (Horn, 1971). Typical values for excitation and emission wavelengths are in the region of 380 and 430 nm, respectively. Some variations in excitation and emission wavelength and fluorescence intensity are observed with ecdysteroids (Koolman, 1980).

3.3.3.1.2. Mass spectrometry Mass spectrometry (MS) has been invaluable in the elucidation of ecdysteroid structures and has been particularly useful for insect samples containing low levels of ecdysteroids. Most of the early work on ecdysteroids has been performed using relatively unsophisticated direct introduction techniques (electron impact, EI), but new ionization techniques are now increasingly employed.

3.3.3.1.2.1. Modes of ionization
3.3.3.1.2.1.1. Electron impact (EI-MS) In EI-MS, an electron beam is used for the ionization and the collision will break the molecule into several characteristic fragments. With nonvolatile substances like ecdysteroids, the use of a 70 eV electron beam results in extensive fragmentation. The abundant fragments correspond to the steroid nucleus or to the side chain and are highly informative for structural elucidation.

3.3.3.1.2.1.2. Chemical ionization (CI-MS) This method uses a reagent gas that is ionized by the electron beam and gives rise to a set of ions that in turn can react with ecdysteroids (Lafont *et al.*, 1981). The ionization reaction proceeds as follows:

$$M + HR^+ \rightarrow MH^+ \text{ (pseudo-molecular ion)} + R$$

$$M + HR^+ \rightarrow MHR^+ \text{(adduct ion)}$$

where R = the reagent gas, e.g., ammonia. The relative intensity of these ions is rather high. Among the various reagent gases, ammonia is most widely used, giving both MH^+ and $(M+NH_4)^+$ ions of high intensity. This method is of interest for the determination of the molecular mass (M) of ecdysteroids. Both positive and negative ionization can be used. The CI/D techniques were analyzed in depth by Lusby *et al.* (1987) who considered the role of

Table 1 Ecdysteroids identified (and isolated in most cases) from insects (see also Rees, 1989; for a complete list of ecdysteroids and for structures, see Ecdybase)

Ecdysteroid	*Species*	*Reference*

parameters such as source pressure and source temperature on fragmentation.

3.3.3.1.2.1.3. Field desorption (FD-MS) With FD-MS, ionization proceeds in a high electrostatic field; such conditions allow ecdysteroid molecules to lose one electron (→ M^+) without excessive heating. In such cases, the organic molecules have not received any large amount of energy and, therefore, almost no fragmentation is observed (Koolman and Spindler, 1977).

3.3.3.1.2.1.4. Fast-atom bombardment (FAB-MS) FAB-MS uses a beam of neutral atoms (argon or xenon) bearing a high kinetic energy for the ionization of involatile ionic or nonionic compounds present either in the solid state or as a solution in a glycerol matrix. FAB-MS is particularly suitable for polar ecdysteroids – phosphate conjugates (see e.g., Isaac *et al.*, 1982b; Modde *et al.*, 1984), ecdysonoic acids (Isaac *et al.*, 1984) – but of course it works also with nonionic ecdysteroids (Rees and Isaac, 1985). Sodium or potassium salts of conjugates and ecdysonoic acids give, respectively, $[M+Na]^+$ and $[M+K]^+$ ions. FAB^+ has been used to characterize fatty acyl derivatives of ecdysteroids (Dinan, 1988), but FAB^- can also be used (Wilson *et al.*, 1988a). When using a deuterated matrix, extensive deuterium exchange takes place and it allows the number of hydroxyl groups present in the molecule to be determined (Pís and Vaisar, 1997).

3.3.3.1.2.1.5. Electrospray (ES-MS) ES-MS has been introduced more recently (Hellou *et al*., 1994). It allows a high intensity of molecular ions to be obtained and is recommended for fragile molecules. Moreover, it can be conveniently coupled with HPLC for in-line analysis.

3.3.3.1.2.2. Low/high-resolution mass spectrometry (HR-MS) All the above methods provide low-resolution mass spectra. Such data result, in fact, from an approximation, as the exact molecular mass of atoms (with the exception of the ^{12}C carbon atom, which by definition is equal to 12) is not a whole number (for example, the mass of ^{1}H is 1.00783 and that of ^{16}O is 15.99491). By using high-resolution instruments, the mass resolution is much increased and the masses of fragments can be obtained with a great accuracy, allowing the spectroscopist to unambiguously determine the elementary composition of ions and of their parent molecules. This technique has fully replaced the former elementary analysis.

3.3.3.1.2.3. Tandem mass spectrometry (MS-MS) The determination of fragment structure and filiation is by no means easy. The MS-MS techniques correspond to the sequential operation of several chambers (quadrupoles) where fragment separation takes place. Thus, the first quadrupole is used to select one ion, and following the passage of that ion through a "fragmentation cell," the second one is used to analyze the further fragmentation of this selected ion. An extensive analysis of this type allows the establishment of genetic relationships between all the observed fragments and is of considerable help in the understanding of fragmentation mechanisms. The same method can also be used to search for the presence of a specific compound in a crude mixture (Mauchamp *et al*., 1993).

3.3.3.1.2.4. General rules for mass spectrometry The fragmentation patterns of ecdysteroids are dominated by ions resulting from the ecdysteroid nucleus and those due to the side chain (Nakanishi, 1971; **Figure 4**). Because of the ready elimination of water from these polyhydroxy compounds, molecular ions, if present, are usually weak (<1%) when using EI-MS, although [M-18]$^{+}$ ions are often readily apparent. Indeed, the high mass region of the spectra of ecdysteroids tends to be characterized by ions 18 mass units apart resulting from the sequential losses of water (Horn, 1971). The presence of a 20,22-vicinal diol allows the cleavage of the side chain (2), giving rise to a prominent fragment at m/z 99 for 20E (otherwise dependent on the structure of the side chain), frequently forming the base peak of the EI spectrum. An ion at m/z 81 is also frequently observed, which probably results from the elimination of water from the side chain fragment (Horn, 1971; Nakanishi, 1971). In the absence of a 20,22-diol, fragmentation (1) between C_{17} and C_{20} is observed. This cleavage is less dominant than the 20,22-scission, and the result is a more complex pattern. Where the side chain has been modified to include methyl or ethyl substituents at C_{24} (e.g., the makisterones A and C), the fragments at m/z 99 and 81 are replaced by ions 14 and 28 mass units higher (Nakanishi, 1971).

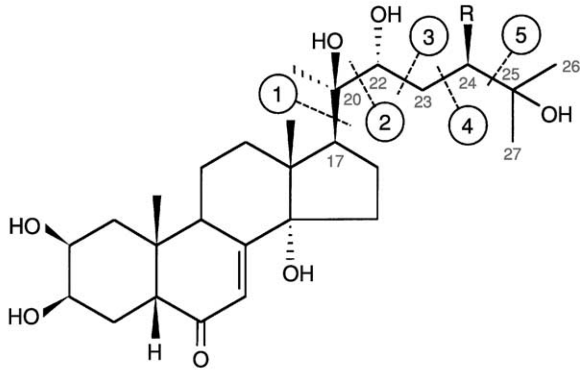

Figure 4 Major and minor fragmentations of ecdysteroid side chain. 1: C_{17}–C_{20} cleavage; 2: C_{20}–C_{22} cleavage (major if 20,22-diol); 3: C_{22}–C_{23} cleavage (minor); 4: C_{23}–C_{24} cleavage (if branching at C_{24}); 5: C_{24}–C_{25} cleavage (for TMS ethers).

3.3.3.1.3. Nuclear magnetic resonance (NMR) NMR spectroscopy is the method of choice for determining the structure of ecdysteroids. Proton ^{1}H-NMR and carbon ^{13}C-NMR are of general use, whereas the use of ^{31}P-NMR is restricted to phosphate conjugates (Hétru *et al*., 1985; Rees and Isaac, 1985) and will not be discussed here.

Obtaining a high-quality ^{1}H-NMR spectrum using modern equipment requires about 50 μg of a pure compound and this is generally sufficient to determine elementary changes like epimerization, appearance of an extra-OH group, or the position involved in a conjugation process. More important changes require ^{13}C-NMR studies, which until recently required amounts in the milligrams. Complete NMR spectra of E and 20E have been published (Kubo *et al*., 1985b; Girault and Lafont, 1988; Lee and Nakanishi, 1989), and general tables are given in several reviews (e.g., Hoffmann and Hétru, 1983; Horn and Bergamasco, 1985; Rees and Isaac, 1985; see also Ecdybase website). Most NMR data have been obtained using C_5D_5N as solvent, except for very apolar compounds (apolar conjugates or acetate derivatives analyzed in $CDCl_3$) and polar conjugates (analyzed in D_2O). These

solvents may be of interest for use with specific compounds in connection with either solubility problems or the presence of signals, which would be masked by signals due to the classical solvents. For ^{1}H-NMR studies using modern machines, the water solubility of many common ecdysteroids is high enough to obtain excellent spectra (Girault and Lafont, 1988).

3.3.3.1.3.1. Proton NMR There have been spectacular improvements in proton NMR with the introduction of high-field machines and sophisticated software, and this has resulted not only in the possibility of using smaller amounts of ecdysteroids but also of obtaining more information from the spectra. Classical proton NMR spectroscopy (in C_5D_5N) allows the easy determination of methyl groups (usually C_{18}, C_{19}, C_{21}, C_{26}, and C_{27}, δ 0.8–1.4 ppm) and of a few additional signals corresponding to 7-H (vinylic proton, δ *ca.* 6.2 ppm) and to primary or secondary alcoholic functions (2-H, 3-H and 22-H δ 4.0–4.2 ppm). Other signals (CH or CH_2 groups) overlap in the same area of the spectrum (δ 1.5–2.3 ppm), with the noticeable exception of 9-H (δ *ca.* 3.5 ppm) and 5-H (δ *ca.* 3.0 ppm) (Horn, 1971). Furthermore, two-dimensional techniques such as 2D-COSY and relayed correlated spectroscopy (COSY) have allowed the complete assignment of all protons of the ecdysone molecule (Kubo *et al.*, 1985a; Girault and Lafont, 1988). The proton NMR spectrum strongly depends upon the solvent and, to a lesser extent, on the temperature used. In most cases the solvent used was C_5D_5N or $CDCl_3$ (for acetate derivatives essentially), but for some compounds such data are lacking and the available spectra were obtained in D_2O, CD_3OD, …, so they are more difficult to compare. Coupling constants also provide useful information concerning the stereochemistry of the ecdysteroid molecule, and, for example, they allow 3α- and 3β-OH compounds to be distinguished.

3.3.3.1.3.2. Carbon-NMR The introduction of ^{13}C NMR (Lukacs and Bennett, 1972) represented a major advance in the determination of ecdysteroid structures. The signals of the carbon atoms are spread over 200 ppm. Thus, ^{13}C NMR spectra are better resolved than ^{1}H spectra. Due to the low natural abundance of ^{13}C, relatively large samples (≥10 mg) are required. Off-resonance decoupled spectra show the coupling of carbon atoms to protons, allowing the carbons to be distinguished from the number (0–3) of protons they bear and allowing an easier interpretation of spectra.

New methods have recently become available for collecting ^{13}C information thanks to inverse correlations with proton signals: the heteronuclear multiple-quantum correlation (HMQC) and the heteronuclear multiple-bond correlation (HMBC), which make use of the direct ($^{1}J^{13}$C-H) and long range ($^{2}J^{13}$C-H and $^{3}J^{13}$C-H) couplings, respectively (**Figure 5**; Girault, 1998); they allow ^{13}C data to be obtained with less than 500 μg of ecdysteroid. The production of higher field instruments (up to 800 MHz) will continue to reduce sample requirements (to 100 μg or even less, if completely pure).

3.3.3.2. Methods of Purification

Ecdysteroids form a group of rather polar compounds and, as a consequence, their extraction is usually performed using a polar solvent such as MeOH. The next step usually involves one or more solvent partitions with the aim of removing the bulk of polar and nonpolar contaminants prior to chromatography (**Figure 6**).

3.3.3.2.1. Extraction procedures Usually, a polar solvent (MeOH, at least 10× sample weight v/w) is used. Two or three repeats are necessary to extract ecdysteroids quantitatively. Alternative solvents include the less toxic EtOH, or Me_2CO, MeCN, $MeOH$-H_2O or H_2O. Extraction can be performed at room temperature, but slight heating (<60 °C) or even refluxing conditions (Soxhlet apparatus) may significantly improve its efficiency.

3.3.3.2.2. Partition techniques The crude extract is concentrated under reduced pressure to give an oily residue. The rather peculiar polarity of ecdysteroids allows their purification by solvent partitioning. This of course applies to compounds having a polarity in the same range as E and 20E. In the cases where polar or apolar ecdysteroids are present (e.g., phosphate or acyl esters), it is clear that those derivatives will partition in a very different way according to their respective polarity, and they may be lost.

3.3.3.2.2.1. Solvent partitioning In early studies (see Horn, 1971), the initial partition was made between an aqueous concentrate and Bu-1-OH. The Bu-1-OH residue, into which the ecdysteroids were extracted, was then partitioned between aqueous MeOH and hexane to remove nonpolar material such as lipids. However, reversing this order of operations was found to be beneficial and led to reduced emulsion formation during the partition step and less problems with frothing during evaporation. Other suitable solvents for removing lipids include hexane-MeOH (7:3, v/v), light petroleum (b.p. 40–60 °C), or Pr-1-OH-hexane (3:1, v/v), the

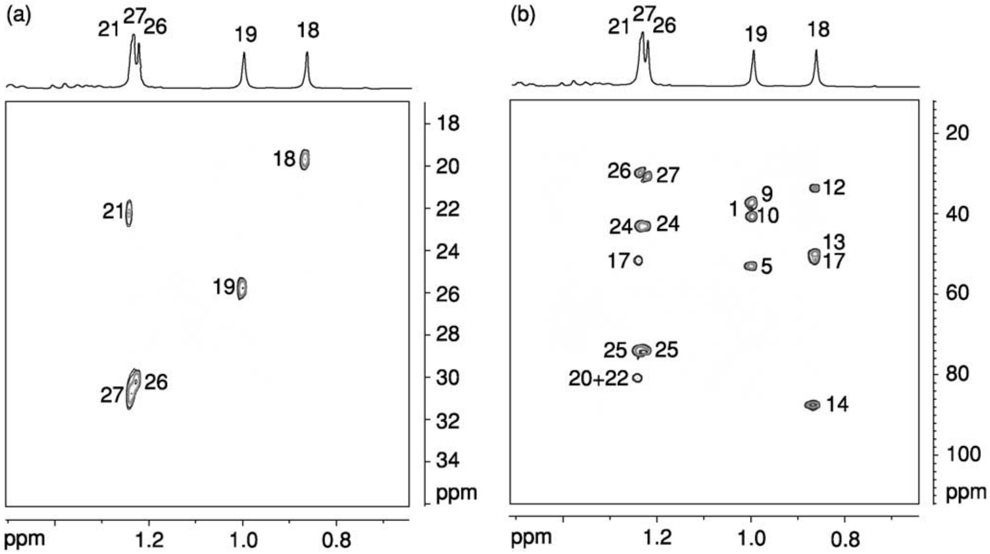

Figure 5 Inverse correlation NMR spectra of 20-hydroxyecdysone in D_2O. (a) Heteronuclear multiple-quantum correlation allows the observation of the direct $^1J^{13}$C-H couplings (e.g., between the 18-Me protons and C-18); (b) Heteronuclear multiple-bond correlation allows the observation of $^2J^{13}$C-H (e.g., between 18-Me protons and C-13) and $^3J^{13}$C-H (e.g., between 18-Me protons and C-12, C-14, and C-17) long-range couplings. (Courtesy of Dr J.-P. Girault.)

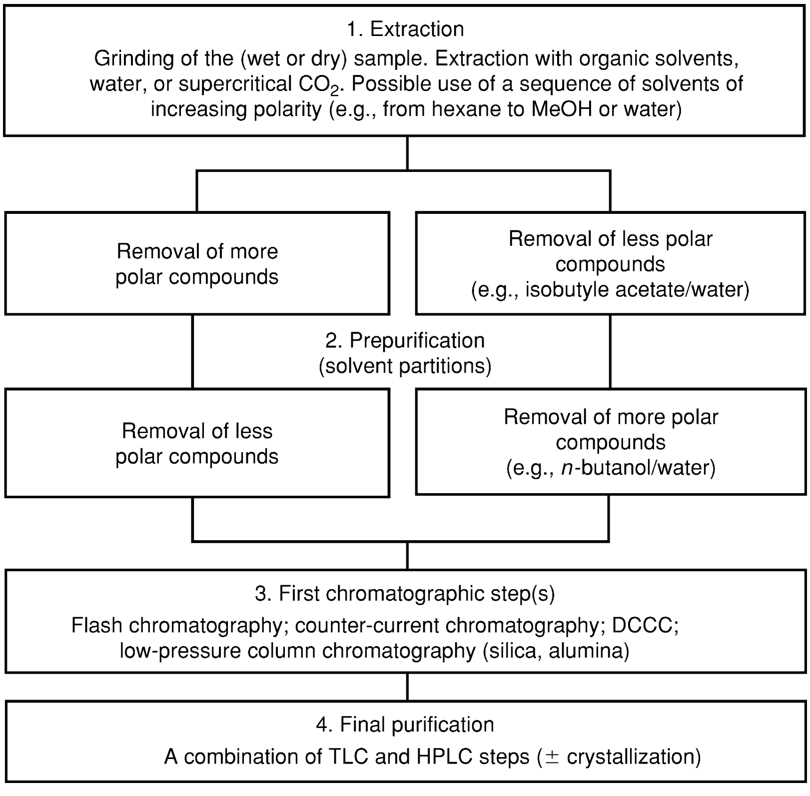

Figure 6 Example of an extraction and purification chart for the large-scale isolation of ecdysteroids. (Reprinted with permission from Lafont, R., Morgan, E.D., Wilson, I.D., **1994b**. Chromatographic procedures for phytoecdysteroids. *J. Chromatogr. 658*, 31–53; © Elsevier.)

ecdysteroids remaining in the aqueous phase. The addition of $(NH_4)_2SO_4$ improves phase separation. The separation of polar impurities from the ecdysteroids can be achieved by partition between H_2O and Bu-1-OH (ecdysteroids partition into the organic phase) and H_2O-EtOAc (ecdysteroids remain in the aqueous phase). The major factors governing the choice of solvent partition system

are the type of contaminants to be removed (i.e., mainly lipids or mainly polar compounds, etc.) and the nature of the ecdysteroids to be isolated. Thus, the addition or removal of one-OH group, or conjugation to polar (e.g., sulfate) or nonpolar (e.g., acetate or fatty acyl) groups can significantly affect partition ratios. A combination of two successive partitions allows elimination of both polar and apolar contaminants. The use of two systems having one solvent in common avoids the need for an evaporation step between the two partitions. It is thus possible to combine first $CHCl_3/H_2O$ followed by H_2O/Bu-1-OH. $CHCl_3$ can be replaced by a more polar organic solvent, such as isobutyl acetate that, allows ecdysteroids to remain in the water phase (Matsumoto and Kubo, 1989).

3.3.3.2.2.2. Counter-current distribution (CCD) Counter-current distribution between Bu-1-OH and H_2O is effective for removing polar contaminants and several other systems have been successfully used in the past (Horn and Bergamasco, 1985). For instance, Butenandt and Karlson (1954) used this method to purify ecdysone from *Bombyx* pupae by means of Craig countercurrent distribution with butanol-cyclohexane-water (6:4:10, v/v/v). This method allowed an efficient separation of two different fractions containing E and 20E, respectively. The same two ecdysteroids were also isolated from an extract of 15 kg *Calliphora* pupae (Karlson, 1956).

3.3.3.2.2.3. Droplet counter-current chromatography (DCCC) DCCC provides an efficient means for purifying samples up to the gram range. It belongs to the family of liquid–liquid partition chromatographic methods. In favorable cases, DCCC can enable the preparation of pure compounds (Kubo *et al*., 1985a). Generally, a subsequent HPLC step is required to get pure ecdysteroids. In a related procedure, high-speed countercurrent chromatography (HSCCC), the column is a multilayer coil and efficient mixing is achieved through planetary rotation (Ito, 1986). The centrifugal forces allow separations to be achieved within hours instead of days with DCCC.

3.3.3.2.3. Column chromatography (low pressure)
3.3.3.2.3.1. Preparative columns This technique can be easily scaled-up according to sample size; it just suffices to keep a low sample to sorbent ratio. It can be used with various stationary phases (NP: silica, alumina; RP: hydrophobic resins, polyamide, or C_{18}-bonded silica; ion-exchange phases, etc.). Elution usually proceeds with a step-gradient of the mobile phase with increasing eluting power; fractions are collected and assayed, for example, by TLC or HPLC.

3.3.3.2.3.2. Small columns and/or disposable cartridges
3.3.3.2.3.2.1. Normal phase Low-pressure chromatography on a small column was used in very early methods for the fractionation of crude extracts: silica or alumina columns (normal phase systems) were generally eluted with binary mixtures, e.g., a step-gradient of alcohol in chloroform or benzene.

3.3.3.2.3.2.2. Reversed phase The availability of hydrophobic phases (resins like Amberlite® or hydrocarbon-bonded silica) has led to a complete renewal of the early procedures. Small cartridges or syringes containing 0.2–1 g of HPLC phase are ideally suited for a rapid clean up of small samples (Lafont *et al*., 1982; Watson and Spaziani, 1982; Pimprikar *et al*., 1984; Rees and Isaac, 1985; Lozano *et al*., 1988b; Wilson *et al*., 1990b). They can also be used for desalting purposes, e.g., direct adsorption of ecdysteroids from culture media, from buffers used for enzymatic hydrolysis of conjugates, or from reversed phase HPLC fractions when an involatile buffer is used.

3.3.3.3. Methods of Separation

The general characteristics of separation are summarized in **Table 2**.

3.3.3.3.1. Thin-layer chromatography (TLC, HPTLC, OPLC)
3.3.3.3.1.1. Chromatographic procedures Normal-phase (absorption) chromatography on silica gel has been used extensively for the isolation of ecdysteroids and for metabolic studies (Horn, 1971; Morgan and Poole, 1976; Morgan and Wilson, 1989).

3.3.3.3.1.1.1. Normal-phase and reversed-phase systems A general normal phase system consists of 95% EtOH-$CHCl_3$ (1:4, v/v). For reproducible results, plates should be heated for 1 h at 120 °C, and then deactivated to constant activity over saturated saline, and TLC tanks should be saturated with the vapor of the solvent used for the chromatography before the plates are developed. Reversed-phase TLC on either bonded or paraffin coated plates has been widely used (Wilson *et al*., 1981, 1982b; Wilson, 1985). Bonded silicas with various alkyl chain lengths of C_2 to C_{18} (or alternatively, various degrees of coating) are available and all seem

GLC	Filled or capillary columns	FID ECD MS	Requires derivatization	Poole *et al.* (1975), Bielby *et al.* (1986), Evershed *et al.* (1987)

TLC, thin-layer chromatography; AMD, automated multiple development; NP, normal-phase; RP, reversed-phase; HPTLC, high-performance thin-layer chromatography; OPLC, over-pressure thin-layer chromatography; SFC, supercritical fluid chromatography; DCCC, droplet counter-current chromatography; CE, capillary electrophoresis; MCE, micellar CE; GLC, gas-liquid chromatography; MS, mass spectrometry; IR, infrared; NMR, nuclear magnetic resonance; FIR, flame ionization detector; ECD, electron capture detector.

suitable for ecdysteroids. MeOH-H_2O, Pr-2-OH-H_2O, EtOH-H_2O, MeCN-H_2O, and Me_2CO-H_2O solvent systems have been used for chromatography; MeOH-H_2O mixtures are most commonly used (Wilson *et al.*, 1981).

3.3.3.3.1.1.2. Two-dimensional TLC A given biological sample can contain a very complex mixture of ecdysteroids. In such cases, two-dimensional techniques have proved to be very efficient: e.g., silica plates developed with (1) toluene-Me_2CO-EtOH-25% aqueous ammonia (100:140:32:9 v/v), then (2) $CHCl_3$-MeOH-benzene (25:5:3 v/v) (Báthori *et al.*, 2000).

3.3.3.3.1.1.3. Visualization techniques Detection of ecdysteroids on the TLC plate can be accomplished using a variety of techniques of varying specificities. Non-specific techniques include iodine vapors or heating in the presence of ammonium carbonate, which produces fluorescent spots or fluorescence quenching when a fluor (ZnS) is incorporated into the silica. More specific reagents, such as the vanillin-sulfuric acid spray, can be used to give spots of characteristic color (Horn, 1971). A slightly more specific fluorescence reaction than that obtained using ammonia detection can be achieved by spraying the plate with sulfuric acid.

3.3.3.3.1.1.4. Scanners Plate analysis can benefit from the wide array of available detectors (scanners) such as UV, UV-Vis, fluorescence, FT-IR, radioactivity, or mass spectrometry (Wilson *et al.*, 1988a, 1990a, 1990c).

3.3.3.3.1.2. General rules for TLC Ecdysteroid behavior on TLC is directly related to the number and position of free hydroxyl groups and the presence of various substituents. The migration of a given compound is given by its R_f (= reference front), defined as [migration of the substance/migration of the solvent front]. From the R_f value, another parameter can be calculated, the R_m, defined as [$R_m = \log(1/R_f - 1)$]. A single modification of an ecdysteroid results in a change in its R_m, expressed as ΔR_m which is to some extent characteristic of the modification (Koolman *et al.*, 1979).

3.3.3.3.1.3. New TLC techniques Several methods providing improved resolution when compared with conventional TLC are available.

3.3.3.3.1.3.1. Automated or Programmed multiple development (AMD and PMD) In this system, the plate is developed repeatedly with the same solvent, which is allowed to migrate further and further with each development. This method allows a reconcentration of ecdysteroids at each run, in particular by suppressing tailing, and this finally results in sharper bands and improved resolution (Wilson and Lewis, 1987).

3.3.3.3.1.3.2. Overpressure thin-layer chromatography (OPLC) In OPLC, the plate is held under an inert membrane under hydrostatic pressure (*ca.* 25 bar) and the solvent is forced through the layer by an HPLC pump. Therefore, the flow of the solvent is controlled and is no longer due to capillarity, and the plate can be developed within minutes. To be efficient, this technique requires the use of HPTLC plates. OPLC has been used with ecdysteroids in only a few instances (Read *et al.*, 1990).

3.3.3.3.2. High-performance liquid chromatography (HPLC) HPLC is the most popular technique for ecdysteroid separations, both for analytical and preparative purposes. It offers a wide choice of techniques that can be optimized for polar or apolar metabolites. The identification of any ecdysteroid by comigration with a reference compound must rely on the simultaneous use of several (at least two) different HPLC systems, generally one normal-phase (NP) and one reversed-phase (RP) system (reviews: Lafont *et al.*, 1980, 1981; Touchstone, 1986; Lafont, 1988; Thompson *et al.*, 1989; Lafont and Wilson, 1990).

3.3.3.3.2.1. Chromatographic procedures

3.3.3.3.2.1.1. Normal phase (NP) systems Silica columns are usually run using mixtures of a chlorinated solvent (e.g., CH_2Cl_2, dichloroethane) and an alcohol (e.g., MeOH, EtOH, Pr-2-OH). Water added to just below saturation partially deactivates silica and this results in more symmetrical peaks; a classical mixture is CH_2Cl_2–Pr-2-OH–H_2O (Lafont *et al.*, 1979). The respective proportions of the three components can be adapted to suit the sample polarity. Thus, specific mixtures can be prepared for nonpolar compounds, e.g., acetates or E precursors (125:15:1 v/v/v), for medium-polarity compounds (125:25:2 or 125:30:2 for E and 20E), or for more polar ecdysteroids (125:40:3 for 26-hydroxyecdysteroids) including glycoside conjugates (100:40:3).

Polar bonded columns (-diol or -polyol,-APS = aminopropylsilane,) can also be used instead of silica (Dinan *et al.*, 1981). Diol-bonded columns have been used with the phasmid *Carausius morosus* for the separation of a wide array of metabolites (Fournier and Radallah, 1988), whereas the APS phase proved particularly efficient for the separation of mixtures of 3α-OH, 3β-OH, and 3-oxo ecdysteroids (Dinan *et al.*, 1981). In addition, these columns allow the use of gradients without the problems linked with the long re-equilibration times encountered with silica. CH_2Cl_2-based solvents, although very efficient for chromatographic separations, suffer from a high UV-cutoff and the quenching properties of this compound, which preclude diode-array detection or efficient in-line radioactivity monitoring (see below). This problem may be overcome with cyclohexane based mixtures (Lafont *et al.*, 1994a), which also display a different selectivity.

3.3.3.3.2.1.2. Reversed-phase systems C_{18}-bonded silicas are the most widely used phases, with elution performed with MeOH-H_2O. MeCN-H_2O or MeCN-buffer mixtures, and are more efficient, especially when polar conjugates and/or ecdysonoic acids are present. The use of ion suppression, e.g., using an acidic buffer, is absolutely essential in the case of polar conjugates or 26-acids. Otherwise, the ionized molecules do not partition well, resulting in variable retention times. Systems have been designed for polar or apolar metabolites, both of which may exist within the same animal. The use of various pHs (Pís *et al.*, 1995a) can modify selectively the retention time of polar (ionizable) metabolites and give access to the pK value of ionizable groups, which can help to characterize conjugates.

3.3.3.3.2.1.3. Detection procedures Several types of detectors can be used for the monitoring of ecdysteroids in the eluates.

UV detector. Ecdysteroids possess a chromophore that is strongly absorbing at ~245 nm, which allows the easy detection of 10 pmol amounts.

Fluorescence detector. There have been several attempts to prepare fluorescent derivatives of ecdysteroids. The potential interest is great, as this would enhance the sensitivity of detection by at least 100 times and possibly also the selectivity as compared to UV. Precolumn or postcolumn derivatization can be used. There are several prerequisites for precolumn reactions: (1) they must be simple and give a single derivative for each ecdysteroid; (2) they must be quantitative, even at very low concentrations of

ecdysteroids present in a crude sample; (3) they must be specific; and (4) the excess reagent (if fluorescent itself) must be removed prior to HPLC analysis. Two approaches have been described: the first used phenanthrene boronic acid (Poole *et al.*, 1978), which is specific for diols and would therefore react also with sugars; the second used 1-anthroyl nitrile (Kubo and Komatsu, 1986), which reacts with alcohols, in this case the 2-OH of ecdysteroids. Interest in the second case would essentially be increased sensitivity, but it is not a specific reaction in that the authors use the same reagent for the determination of prostaglandins! These methods have not received further applications, and we must emphasize that the use of precolumn derivatization would negate one major advantage of HPLC over GLC. Postcolumn derivatization could make use of the sulfuric acid-induced fluorescence (see above), but this has not been investigated.

Diode-array detectors. Such detectors represent valuable tools since they provide the absorbance spectrum of all eluted peaks. Thus, in the case of ecdysteroids, whether or not a compound that comigrates with a reference ecdysteroid has a UV absorbance with a maximum at 242 nm can be directly checked. This is an additional criterion for assessing the identity of peaks and it works equally well with very small amounts of ecdysteroids (less than 100 ng).

Radioactivity monitors. On-line radioactivity measurement in ecdysteroid metabolic or biosynthesis studies is of considerable interest because: (1) it provides an immediate result; (2) it saves time and avoids the need for collecting many fractions, filling scintillation vials, and waiting for their measurement; (3) it provides direct comparison with the signal of another detector, e.g., UV monitor, and allows an easy check for the coelution of radioactive peaks with reference compounds; and (4) it does not significantly decrease the resolution when compared with the UV signal: this means that at a flow rate of 1 ml min^{-1} for the column effluent and 3 ml min^{-1} for the scintillation cocktail, with a detector cell size of 0.5 ml, the result is equivalent or even better than collecting 0.2 ml fractions (i.e., 200 tubes for a 40 min analysis).

Mass spectrometry (MS). On-line HPLC-MS provides useful information on the structure of ecdysteroids eluting from the column, and has become a routine technique thanks to the thermospray and electrospray techniques. Two groups (Evershed *et al.*, 1993; Marco *et al.*, 1993) reported the successful use of HPLC-MS with ecdysteroids. These techniques work in the nanogram range with single ion monitoring (SIM) detection (Evershed *et al.*, 1993). Their use with acetonide derivatives results in a stabilization of the molecules and the production of abundant molecular ions (Marco *et al.*, 1993). A further improvement was obtained with atmospheric pressure chemical ionization (APCI-MS) resulting in a much lower limit of detection – 10 pg with E and 20E (Wainwright *et al.*, 1996, 1997).

Nuclear magnetic resonance (NMR). Using superheated D_2O as eluent, it has been possible to get on-line proton NMR spectra, but this requires high (100–400 μg) amounts of ecdysteroids to be injected on the column (Louden *et al.*, 2002).

3.3.3.3.2.2. Different aims of HPLC

3.3.3.3.2.2.1. Analytical and preparative HPLC Columns of different sizes exist with the same packings, and it is therefore very easy to scale up any chromatographic method. Analytical (i.d. 4.6 mm), semi-preparative (i.d. 9.4 mm), and preparative (i.d. *ca.* 20 mm or more) columns are available. By increasing the flow rate in proportion to the cross-section, one obtains similar separations with increased maximal load.

3.3.3.3.2.2.2. Microbore HPLC Microbore HPLC has been designed essentially for coupling with mass spectrometry. It uses columns of small internal diameter (e.g., 1 mm) run with a reduced solvent flow rate (*ca.* 50 μl min^{-1}), which is compatible with a direct coupling with a mass spectrometer.

3.3.3.3.2.2.3. Quantitative analyses HPLC has been used for the direct quantification of individual ecdysteroids in biological samples. This requires of course high sensitivity because of the low concentrations encountered and adequate sample clean up. Quantification is best obtained if an internal standard is added to the sample either before HPLC analysis, or better, before sample purification (Lafont *et al.*, 1982). Many phytoecdysteroids can be used as internal standards (Wilson *et al.*, 1982a).

The fundamental place of HPLC in ecdysteroid analysis will be exemplified by a detailed analytical protocol applied to locust eggs (**Figure 7**). A combination of HPLC at various pHs and of enzymatic hydrolyses may indeed allow a rational diagnosis of ecdysteroid types present in a given biological extract (**Table 3**).

3.3.3.3.3. Gas-liquid chromatography (GLC) This method was first introduced for ecdysteroids by Katz and Lensky (1970), and developed during the following years (Morgan and Woodbridge,

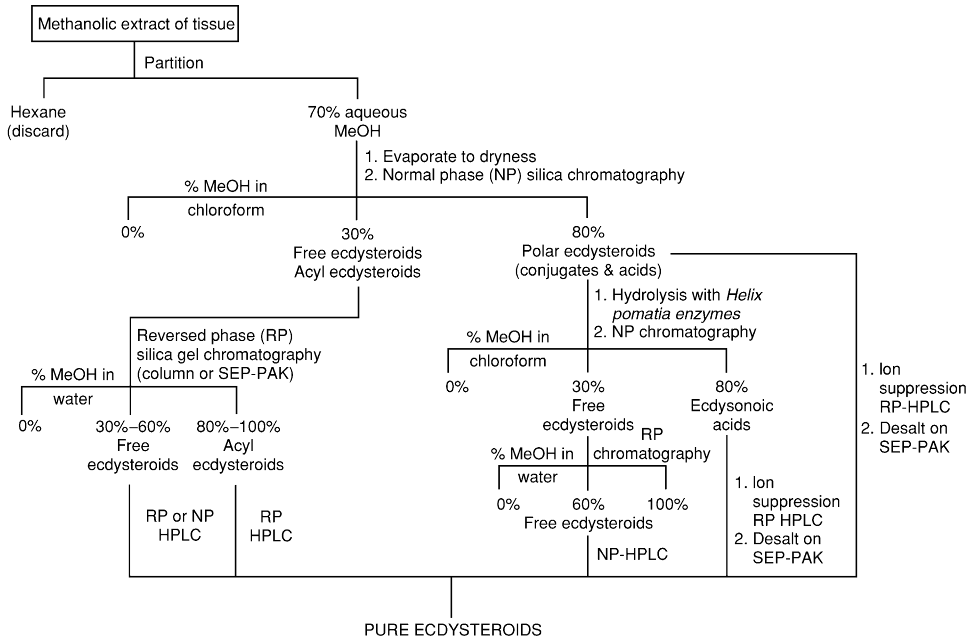

Figure 7 A general procedure for the purification of ecdysteroids combining several chromatographic steps. (From Russel, G.B., Greenwood, D.R., **1989**. Methods of isolation of ecdysteroids. In: Koolman, J. (Ed.), ecdysone from chemistry to mode of action. Georg Thieme Verlag, Stuttgart, p. 102. Reprinted by permission.)

Table 3 Strategy for a rationale diagnosis of ecdysteroids

Polarity	*Electrically charged (Yes/No)*	*pK_a (if applicable)*	*Susceptibility to hydrolysis (Yes/No)*	*Conclusion*
High		6.5–7.0	Y	Phosphate esters
	Y	4.5	N	26-Oic acids
		2.0	Y	Sulfate esters[a]
			Y	Glucosides
Medium			N	26-OH derivatives
	N	–	N	E, 20E and related
Low			N	Precursors
			Y	Acyl esters

[a]Sulfate esters have not yet been found in insects.

1971; Ikekawa *et al.*, 1972; Miyazaki *et al.*, 1973). Despite the advantages possessed by gas-liquid chromatography (GLC) in terms of sensitivity and specificity as compared to other techniques, its use for ecdysteroids has been confined to only a few groups (Borst and O'Connor, 1974; Morgan and Poole, 1976; Koreeda and Teicher, 1977; Lafont *et al.*, 1980; Webster, 1985; Bielby *et al.*, 1986; Evershed *et al.*, 1987, 1990). As all but a few biosynthetic intermediates of ecdysteroids are nonvolatile, it is necessary to convert them into volatile trimethylsilyl (TMS) ether derivatives. Detection can be carried out using either a flame ionization detector (FID, poor sensitivity), or better still, an electron capture detector (ECD) or a mass spectrometer (MS). In the 1970–1980 period, GC-MS represented a reference method for analyzing ecdysteroid mixtures (Lafont *et al.*, 1980).

With filled columns (1–3 m long), chromatography is performed on nonpolar stationary phases such as OV-1 and OV-101 coated on Gas Chrom Q and Gas Chrom P. Typical operation temperatures for the columns are in the range of 280 °C, with carrier gas flow rates of 50 ml min^{-1} (Bielby *et al.*, 1986). Retention behavior on GLC is the result of both molecular mass and polarity, depending on the degree of silylation. Capillary GC using flexible fused silica columns provides improved resolution and sensitivity. Thus, 10 pg (20E) or 100 pg (E) could be detected by GC coupled with mass spectrometric (SIM) detection (Evershed *et al.*, 1987).

3.3.3.3.4. Supercritical fluid chromatography Supercritical fluid chromatography (SFC) uses a supercritical fluid as mobile phase, which behaves like a compressible fluid of very low viscosity, where mass transfer operates very rapidly, allowing the use of high linear velocities and, therefore, very short analysis times without any loss of efficiency. SFC may use either conventional packed HPLC columns or capillary tubes, and the mobile phase is generally supercritical CO2 containing a small amount of an organic modifier, e.g., MeOH (Morgan *et al.*, 1988; Raynor *et al.*, 1988, 1989). Chromatographic parameters that can be monitored are the temperature, the pressure, and the percentage of the organic modifier. Supercritical CO_2 is a nonpolar fluid and, therefore, SFC is more or less equivalent to normal-phase HPLC; the eluting power is increased by adding MeOH. Various types of packed columns can be used, including silica or bonded silica; alternatively, fused silica capillary columns can be used (Raynor *et al.*, 1988). A major advantage of SFC over HPLC is the shorter retention times; compounds elute as sharp peaks and the sensitivity of detection is accordingly increased. A second advantage concerns the high transparency of CO_2 in the infrared (IR), which allows the use of FT-IR detectors. Furthermore, SFC is compatible with both flame ionization detection (the universal detection used with GLC) and mass spectrometry. No derivatization is required, and this represents an important advantage over GLC.

3.3.3.3.5. Capillary electrophoresis (CE) Capillary electrophoresis is a recently introduced technique that allows extremely efficient separation of peptides, oligonucleotides, and also steroid hormones. The migration of substances is due to a combination of electroendosmotic flow of buffer towards the cathode and the (slower) migration of negatively charged solutes towards the anode. CE gives very efficient separations for a wide range of ionized and unionized compounds. As most of the ecdysteroids are not ionizable, CE has to be performed using some form of micellar CE (MCE, also known as MECK or micellar electrokinetic chromatography). In this mode, a surfactant such as sodium dodecyl sulfate (SDS) is added to the buffer at a concentration above its critical micellar concentration. The compounds of interest then partition between the aqueous phase and the micelles as these are drawn through the capillary by the electroosmotic flow. Such an approach has been shown to be well suited to the CE of ecdysteroids. Two types of methodology have been used in CE: with SDS and an organic modifier such as MeOH (Large *et al.*, 1992; Davis *et al.*, 1993); or with SDS and γ-cyclodextrin as modifiers (Yasuda *et al.*, 1993). CE has been used for extracts from the eggs of *Schistocerca gregaria* (Davis *et al.*, 1993) and crayfish hemolymph (Yasuda *et al.*, 1993). The sensitivity of MCE for ecdysteroids was very good and the on-column detection of *ca.* 175 pg of ecdysone was readily achieved. In fact, due to the very small volume that can be injected on the column (5 nl), this corresponds in practice to a much larger sample containing 35 μg ml^{-1} (i.e., a 10 μl sample would have to contain 350 ng ecdysteroid).

3.3.3.4. Methods of Quantification

One can use the physicochemical techniques as discussed above (see **Table 4**) or, alternatively, bioassays and immunoassays (**Table 5**) performed either on crude extracts or on fractions collected after a chromatographic separation (TLC, HPLC).

3.3.3.4.1. Bioassays Various kinds of bioassays are used for testing ecdysteroids from animal or plant extracts, either *in vivo* or *in vitro*. Their purpose may be either the measurement of ecdysteroid concentrations in biological samples (they allowed the isolation of E by Butenandt and Karlson, 1954), to analyze the relative biological activity of various ecdysteroids (structure–activity relationships), or to screen plant extracts for ecdysteroid content in a semiquantitative way.

We may distinguish between assays where disturbances or toxic effects are assessed (e.g., abnormal molting), and bioassays designed to measure a biological activity linked to a normal physiological process or even to quantify hormones. The naturally occurring ecdysteroids exhibit a wide range of molting hormone activities when measured in bioassay systems. Bioassay systems for molting hormones have tended to be based on the larval–pupal molt of a number of dipteran species (e.g., *Calliphora*, *Sarcophaga*, and *Musca*). In these assays, last instar larvae are ligated and those showing no further development of the abdomen are selected for use in the bioassay. Extracts of (pure) compounds are then injected into the abdomen and signs of development (tanning of the cuticle) are sought. The sensitivity of the assay varies depending on the dipteran species used and the assay conditions: in *Calliphora* it is of the order of 5–50 ng per abdomen for 20E versus 5–6 ng for *Musca*. A variation on the rather specialized larval–pupal molt used in the dipteran bioassays is the locust abdomens of fourth instar *S. gregaria* and is based on a larval-to-larval molt. Another useful bioassay, which does not require the injection of the test material, is based on the use of

Table 4 Physicochemical methods of quantification: characteristics and limits of detection

Method	*Limits of detection*	*Specificity*	*References*
Direct or after a chromatographic separation			
UV absorbance (*ca.* 242 nm)	1 μg	Poor	Sardini and Krepinsky (1974)
Chugaev's color reagent (380 nm)	<10 μg	Limited	Kholodova (1977, 1981), Bondar *et al.* (1993)
Sulfuric acid induced fluorescence	10 pg	Limited	Gilgan and Zinck (1972), Koolman (1980)
Bioassay	*ca.* 5 ng	Good	Cymborowski (1989)
Immunoassay	5–10 pg	(Very) good	Porcheron *et al.* (1989)
TLC			
UV absorbance (scanner)	500 ng	Low	Wilson *et al.* (1990c), Báthori and Kalász (2001)
Fluorescence quenching (fluorescent TLC plates)	500 ng	Low	Mayer and Svoboda (1978)
Mass spectrometer			
HPLC			
UV absorbance	<10 ng	Fair	Lafont *et al.* (1982), Wright and Thomas (1983)
Fluorescence (requires derivatization)	<10 pg	?	Poole *et al.* (1978), Kubo and Komatsu (1986, 1987)
Mass spectrometer	50–100 pg	Very good	Evershed *et al.* (1993), Le Bizec *et al.* (2002)
GLC			
Flame ionization detector	50 ng	Poor	Katz and Lensky (1970)
Electron capture detector	1–10 pg	Good	Poole *et al.* (1975, 1980), Bielby *et al.* (1986)
Mass spectrometer	10–100 pg	Very good	Evershed *et al.* (1987)

ligated larvae of *Chilo suppressalis* (Sato *et al.*, 1968). These are simply dipped into methanolic solutions of the test compound of extract. An *in vitro* variation of this assay uses pieces of integument from ligated larvae of *Chilo* and has a reported sensitivity of *ca.* 15 ng per test (Agui, 1973). In all *in vivo* test systems, it is difficult to assess whether the observed biological activity derives from the injected compound or an active metabolite. An obvious example of this is the conversion of 2dE and E into the more active metabolite, 20E (as shown by comparison with their activity in *in vitro* bioassays). The same considerations may apply to 3-oxo (3-dehydro) ecdysteroids.

In vitro systems, where it is possible to determine the biological activity of a compound in the quasi-absence of its metabolism, are therefore very useful for the determination of structure–activity relationships. Among them, a microplate bioassay using a *Drosophila* cell line (B II) was designed by Clément and Dinan, 1991 and Clément *et al.*, 1993 with good sensitivity and accuracy. This assay relies on a turbidimetric measurement of cell density in a system where ecdysteroids inhibit cell proliferation. More recently, new methods have been proposed, which use either *Drosophila* Kc cells transfected with a reporter plasmid containing the 5′ region of the *hsp27* promoter and the firefly luciferase gene (Miki-Mikitani, 1995) or SL2 cells with the addition of an EcR expression plasmid (Baker *et al.*, 2000). Cells were cultured for 24 h in the presence of ecdysteroids, and then cell lysates were used to measure luciferase activity.

A number of *in vitro* bioassay systems exist, including puffing of polytene chromosomes (reviews Bergamasco and Horn, 1980; Cymborowski, 1989) and morphogenesis in imaginal discs. As Bergamasco and Horn (1980) pointed out, in bioassays where quantitative data are sought, the purity of the sample, especially the absence of other active ecdysteroids, is of paramount importance.

3.3.3.4.2. Immunoassays Immunoassay (IA) use antibodies obtained by immunization with ecdysteroids. As ecdysteroids are not directly immunogenic, they must be coupled to a suitable protein before immunization. Generally, they are derivatized to create a carboxylic function which can react with the amino groups of protein carriers (BSA, HSA or thyroglobulin). The protein–ecdysone complex is strongly immunogenic and high titers of antibodies are generally elicited after the first injection.

The specificity of antibodies is rarely absolute, as they generally will recognize both E and 20E, as well as a series of closely related ecdysteroids. The degree of hapten binding by antibodies is primarily determined by the structure of the immunogen, especially as regards the position of the linkage between the ecdysteroid and the protein. For instance, protein esterification via the C_2 hydroxyl on the A-ring or the C_{22} hydroxyl on the side chain will generally result in antisera specificity against ecdysteroid ligands exhibiting molecular changes in either the side chain or the steroid

[a]SAR, structure-activity relationship.

nucleus, respectively (**Figure 8**) (Warren and Gilbert, 1988).

Immunoassays need tracer molecules. In Radioimmune Assay (RIA), tracers are radiolabeled with a high specific activity. Two kinds of analogs are used: commercially available [^{3}H]-ecdysone (50–80 Ci/mmol), and laboratory-made iodinated analogs (up to 2000 Ci/mmol), which provide a higher sensitivity (Hirn and Delaage, 1980). The RIA has several drawbacks due to the utilization of a radioisotope, which requires special precautions, and for that reason other immunoassays have been developed: a chemilumino-immunoassay (CIA), which uses ecdysone-6-carboxy-methoxime aminobutylethyl-isoluminol (ABEI) to form a chemroluminescent tracer (Reum *et al.*, 1984), and enzyme immunoassays (EIA) with an ecdysone derivative coupled to an enzyme, acetylcholinesterase (Porcheron *et al.*, 1989; Royer *et al.*, 1993) or peroxidase (Delbecque *et al.*, 1995; Von Gliscynski *et al.*, 1995).

After incubation of antibodies, tracer, and biological extract (or calibration references), the separation of free and bound fractions is performed in various ways (Reum and Koolman, 1989). The lower limit of sensitivity was estimated, in the best cases, as 4.10^{-10} mol (1.6 pg) (Hirn and Delaage,

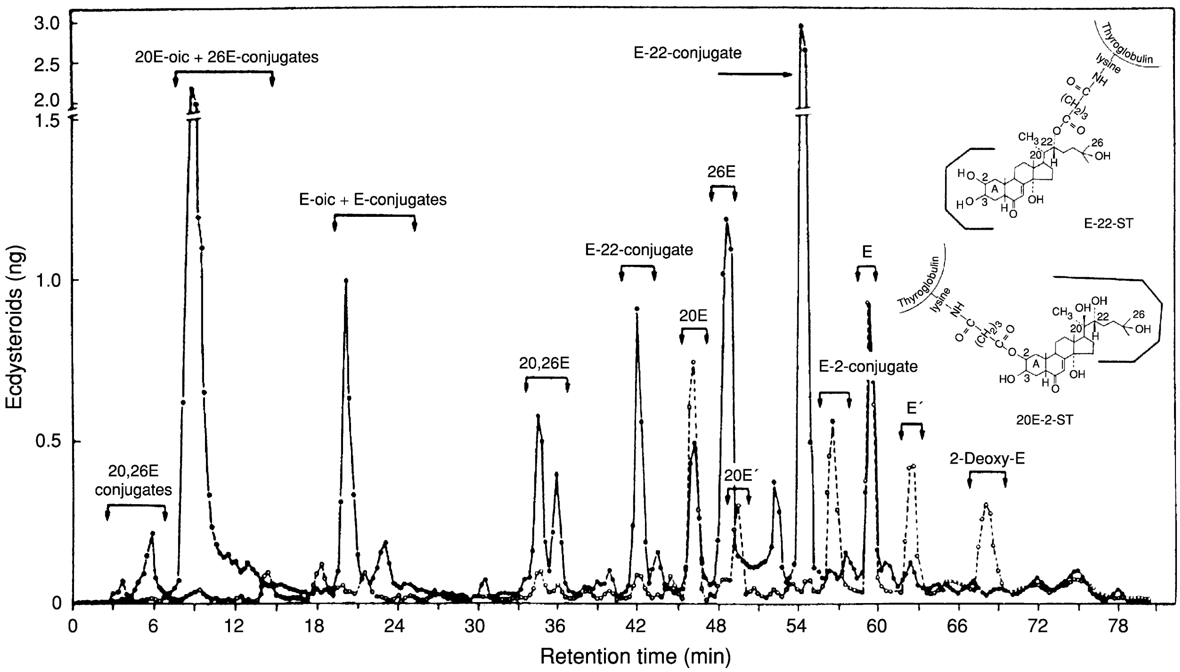

Figure 8 RP-HPLC/RIA analysis of ecdysteroids from the gut of females during day 14 of pupal–adult development in *M. sexta*. The chromatograms show the elution from a C_{18}-silica column by a neutral buffered water/acetonitrile system of a female gut sample. Analysis is by differential RIA employing two complimentary antibodies. One antibody was elicited by an ecdysone-22-succinylthyroglobulin immunogen conjugate (E-22-ST) where the ecdysteroid hapten was conjugated via its C_{22}-hydroxyl group to the immunogenic carrier protein (solid line). The other antibody was elicited by a 20-hydroxyecdysone-2-succinylthyroglobulin immunogen conjugate (20E-2-ST) where the ecdysteroid was conjugated via the C_2 hydroxyl group (dashed line). In general, substrate discrimination by antibodies is greatest for molecules that differ in their architecture at a place far from the point of hapten attachment to the immunogenic protein carrier molecule. E′: 3α-epiE, 20E′, 3α-epi20E; 26E, 26-hydroxyE; 20,26E, 20,26-dihydroxyE; E-oic, ecdysonoic acid; 20E-oic, 20-hydroxyecdysonoic acid; E-22- (or E-2)-conjugate, E conjugated at the 22 (or 2) position. (Modified from Warren *et al.*, **1986**. Metabolism of ecdysteroids during the embryogenesis of *Manduca sexta*. *J. Liquid Chromatography 918*, 1759–1782).

1980) but, in fact, the sensitivity currently achieved by most ecdysteroid immunoassays is in the range of 20–200 fmol (10–100 pg). An example of RIA performed after an HPLC separation is given in Figure 8.

3.3.3.5. Sources of Ecdysteroids

Only a few ecdysteroids are commercially available. All of them have been isolated from plants and they include only four insect ecdysteroids: 2d20E, E, 20E, and makisterone A. Because of its use as an anabolic substance by many bodybuilders (Lafont and Dinan, 2003), 20E can now be purchased in large quantities at a low price. When an ecdysteroid other than the four noted above is required, there are three ways in which it can be obtained: (1) it can be requested from someone who has already isolated (or synthesized) this compound; (2) the molecule can be isolated from an adequate plant source; or (3) it can be synthesized from an available precursor. This does not always require complicated chemistry; Table 6 lists some syntheses that are not highly complex and can be performed in the absence of an experienced chemist.

3.3.4. Ecdysteroid Biosynthesis

3.3.4.1. Sterol Precursors and Dealkylation Processes

Owing to the lack of a squalene synthase (and/or other enzymes), insects are unable to synthesize sterols *de novo* (Clayton, 1964; Svoboda and Thompson, 1985). Consequently, they rely on dietary sterols for their supply. Zoosterols are essentially cholesterol; thus, insects feeding on animal derived food get cholesterol directly. On the other hand, those feeding on plants obtain mainly phytosterols, which differ from cholesterol by the presence of various alkyl substituents (ethyl, methyl, methylene) on carbon 24. However, it should be noted that most plants also contain small but detectable amounts of cholesterol. Nevertheless, many, but not all, phytophagous insect species possess the ability to first dealkylate phytosterols to cholesterol, which is subsequently

Table 6 Just a little bit of chemistry: total or partial synthesis (side-chain modifications) and simple modifications (e.g., oxidation at C-3, removal of -OH groups (e.g., 25-OH), conjugation to acetic acid, fatty acids, glucose, sulfate)

converted in endocrine tissues to the active C_{27} molting hormone 20E. By contrast, some species, mainly Hemiptera and Hymenoptera, are unable to dealkylate phytosterols and consequently produce 24-alkylated ecdysteroids (i.e., C_{28} makisterone A and/or C_{29} makisterone C; Feldlaufer *et al.*, 1986; Feldlaufer, 1989; Mauchamp *et al.*, 1993).

In some cases, due to a combination of specific mechanisms including (1) selective concentration of the dietary cholesterol (Thompson *et al.*, 1963; Svoboda *et al.*, 1980) and/or (2) its selective delivery to steroidogenic organs, the insect can produce mainly C_{27} ecdysteroids even if cholesterol is a very minor sterol component of its diet. The ecdysteroid pool usually represents only 0.1–0.2% of total sterols, as illustrated by the low conversion rate of radioactive cholesterol when injected *in vivo* for long-term labeling studies (e.g., Beydon *et al.*, 1981, 1987).

Finally, some insects have become independent of a dietary sterol supply thanks to the production of sterols by yeast-like or fungal symbionts; this situation has been described in several insect species, particularly in aphids and beetles (Svoboda and Thompson, 1985). Yeast-like symbionts provide mainly 24-alkylated sterols (e.g., ergosta-5,7,24(28)-trienol). Thus, those insects still require a

dealkylation process in order to produce cholesterol (Weltzel *et al.*, 1992; Nasir and Noda, 2003). According to the nature of their dietary sterols and their ability to dealkylate phytosterols, insects produce different ecdysteroids (**Table 7**).

3.3.4.1.1. General scheme of cholesterol formation from phytosterols A given species usually contains a complex sterol cocktail, with a few major compounds and many minor ones. Sterol diversity concerns (1) the number of carbon atoms (27 to 29) as discussed above and (2) the number and position of unsaturations, classically termed Δ: mainly Δ^5 and Δ^7 on the steroid nucleus, and Δ^{22} and Δ^{24} on the side-chain (**Figure 9**). In addition, sterols can be in free or conjugated form, i.e., sterol acyl esters with various fatty acids or sterol acylglucosides, where a sugar moiety is linked both to the 3β-OH of the sterol and to a fatty acid (Eichenberger, 1977; Grunwald, 1980).

Ingested sterols are subjected to the action of several types of enzymes: (1) hydrolytic enzymes (esterases or glycosidases) from the insect gut (see **Chapter 4.5**), which will release free sterols from their conjugates; (2) reductases and/or oxidases; and (3) enzymes involved in the so-called "dealkylation process." Reactions (2) and (3) have been investigated extensively from the late 1960s by a combination of several strategies: feeding experiments with diets containing one particular sterol; *in vivo* metabolic studies with [^{3}H] or [^{14}C] labeled sterols allowing the isolation of labeled intermediates; in vitro enzymatic studies using isolated tissues or cell-free preparations; and observing the effects of various pharmacological inhibitors of reactions known in mammals/humans (i.e., hypocholesterolemic agents). All the biochemical pathways have been fully elucidated, at least with regards to the metabolism of the most common Δ^5 plant sterols (reviews: Fujimoto *et al.*, 1985b; Svoboda and Thompson, 1985; Svoboda and Feldlaufer, 1991; Svoboda and Weirich, 1995; Svoboda, 1999), and are summarized in **Figure 10**.

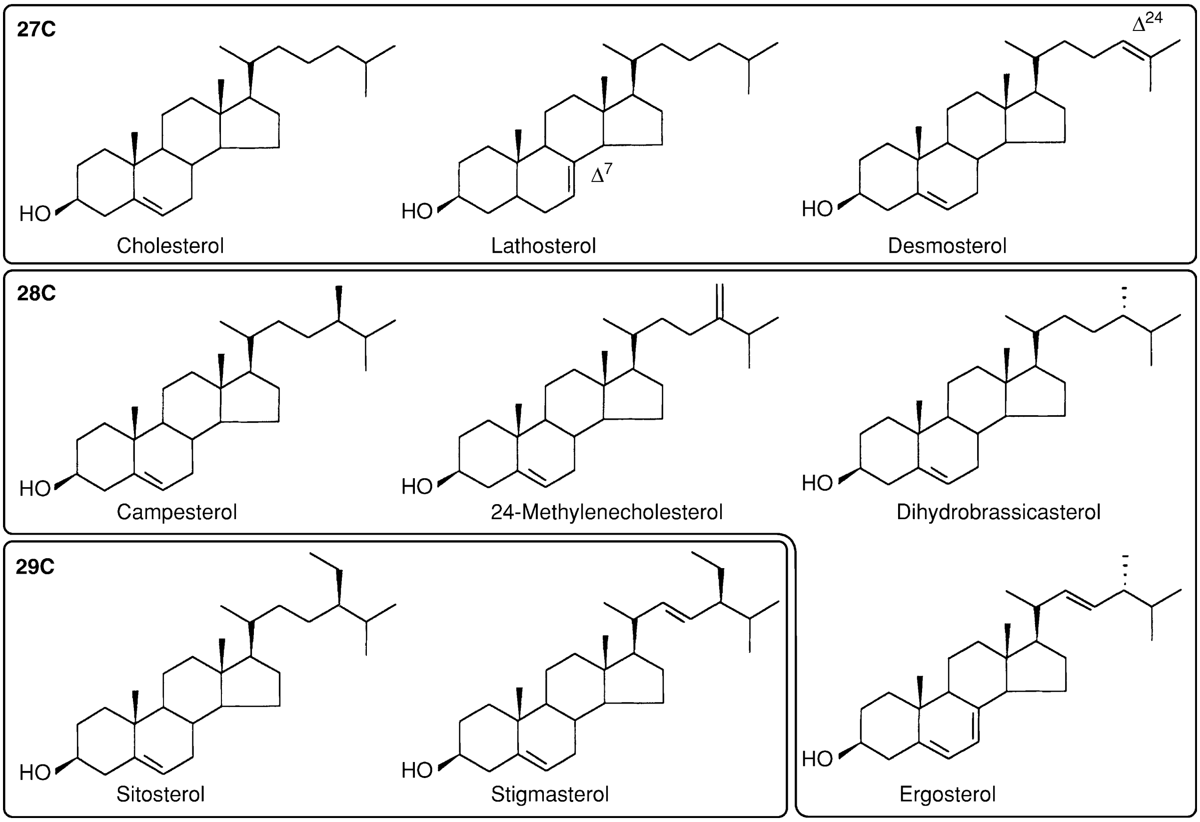

Figure 9 Structures of cholesterol and of representative phytosterols.

3.3.4.1.2. Dealkylating enzymes The first evidence for dealkylation of ergosterol into Δ^{22}-cholesterol was obtained with the cockroach *Blatella germanica* (Clark and Bloch, 1959). Further work, performed in particular with *Manduca sexta* and *Bombyx mori* larvae, allowed the identification of all intermediates. Four to five enzymes are necessary to dealkylate phytosterols. The first three reactions involve the formation of an epoxide intermediate, and the removal of the side chain is accompanied by the formation of a Δ^{24} bond, thus forming desmosterol or its $\Delta^{22,24}$ analog (Figure 10). The second part (one or two steps) concerns the reduction of the side chain. When starting for instance from sitosterol or campesterol, the dealkylation product (desmosterol) bears a single (Δ^{24}) double bond, and can be reduced to cholesterol by most insect species analyzed so far. In the case of insects fed on Δ^{22} sterol (e.g., stigmasterol or ergosterol), the dealkylation product bears a 22,24-diene and two reductases are required. It has been shown that the reduction at C_{22} must precede that at C_{24} and cannot be performed by all insect species (Svoboda and Thompson, 1985).

It was expected that dealkylation takes place in the insect gut. Indeed, cell-free extracts prepared from larval silkworm guts when incubated with adequate intermediates resulted in the formation of desmosterol and cholesterol (Fujimoto *et al.*, 1985b). Midgut microsomes are the most active source of enzymes (e.g., *Spodoptera littoralis*, Clarke *et al.*, 1985), but midgut is not the only active tissue in this respect (Awata *et al.*, 1975). Unfortunately, most of these early experiments were discontinued, and as yet none of these enzymes has been fully characterized.

The desmosterol 24-reductase is present both in insects and vertebrates, catalyzing the last step in cholesterol biosynthesis. There seems to be a significant structural conservation, as the insect enzyme can be inhibited by many hypocholesterolemic agents used in humans to reduce endogenous cholesterol biosynthesis. Indeed, azasteroids and various amines are also active on the insect enzyme and will consequently inhibit insect development (Svoboda and Weirich, 1995), but they cannot be used as insecticides due to their phytotoxicity. Moreover, there is significant sequence conservation between the human and nematode proteins and even human and plant sequences share 30% identity (Choe *et al.*, 1999; Waterham *et al.*, 2001). Unfortunately, available data on insect genomes concern

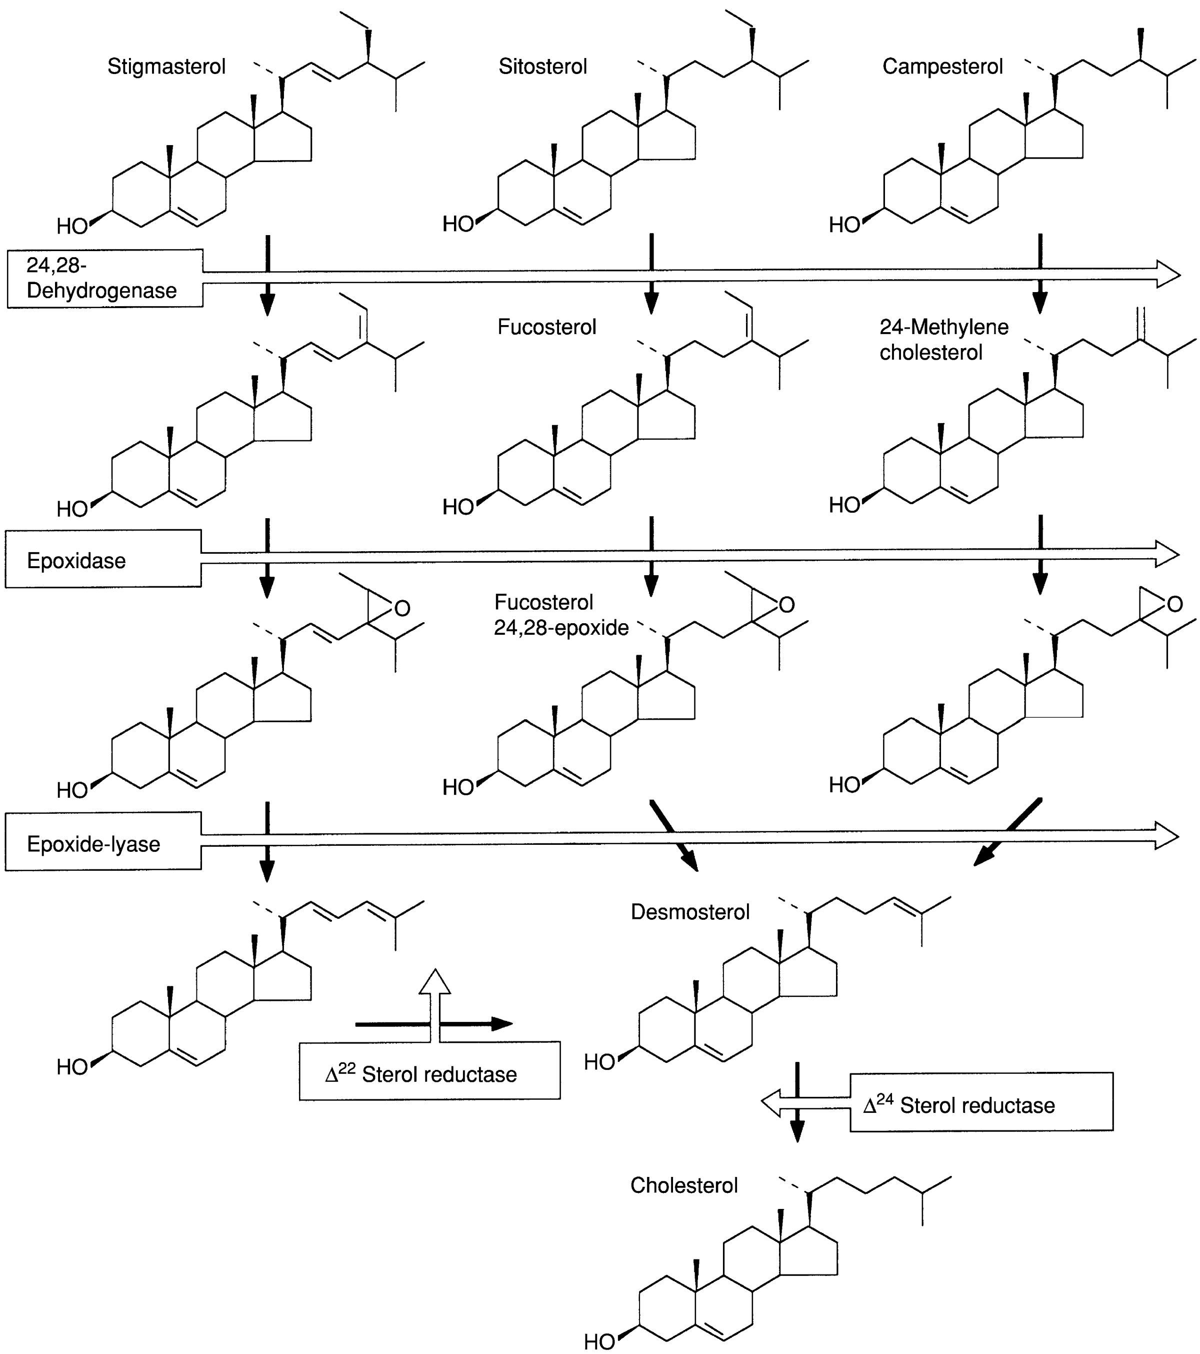

Figure 10 From phytosterols to cholesterol: the dealkylation processes.

species that are believed to be unable to dealkylate phytosterols and thus would lack the corresponding enzyme.

3.3.4.1.3. Variations among insect species Not all phytophagous species that can dealkylate phytosterols use the pathway described in Figure 10. Thus, the Mexican bean beetle, *Epilachna varivestis*, first totally reduces sitosterol (or stigmasterol) to stigmastanol, which is then dealkylated to cholestanol and the latter is then dehydrogenated to lathosterol (Δ^7), the major sterol found in this species (Svoboda *et al.*, 1975). This example highlights the importance of unsaturations present in the steroid nucleus. In some insect species, Δ^7 or $\Delta^{5,7}$ compounds can be the major sterols (Svoboda and Lusby, 1994; Svoboda, 1999), while *Drosophila pachea* has evolved specific requirements for ingesting Δ^7

sterols in order to produce E (Heed and Kircher, 1965; Warren *et al.*, 2001; see Section 3.3.4.2.1). In summary, insects' ability to modify sterol nucleus unsaturations differs greatly between species (Rees, 1985).

In some instances, species unable to dealkylate phytosterols may adapt their physiology to the nature of their sterol diet, e.g., *Drosophila melanogaster*. Apparently unable to dealkylate phytosterols (Svoboda *et al.*, 1989), *D. melanogaster* produces a mixture of 20E and makisterone A, the proportions of which reflect the composition of its sterol diet (Redfern, 1986; Feldlaufer *et al.*, 1995; Pak and Gilbert, 1987). This strategy can operate because in this species E receptors have a very similar affinity for both ecdysteroids (Dinan *et al.*, 1999; Baker *et al.*, 2000) (37). Bees (Hymenoptera) seem to follow a similar scheme (Svoboda *et al.*, 1983; Feldlaufer *et al.*, 1986). Leafcutter ants appear to be unique in that they feed mainly on fungal sterols, which differ from plant sterols in their stereochemistry at C_{24}. As a result, they produce 24-epimakisterone A instead of makisterone A (Maurer *et al.*, 1993). More generally, different enzymatic machinery and/or ecdysteroid receptor specificity among insects will result in different sterol requirements. These are revealed by feeding experiments on defined diets and so represent an aspect of the adaptation of insects to specific foods.

3.3.4.2. The Biosynthetic Pathway of Ecdysteroids from Cholesterol

Although it has received considerable attention (see reviews by Rees, 1985, 1995; Warren and Hétru, 1990; Sakurai and Gilbert, 1990; Grieneisen, 1994; Dauphin-Villemant *et al.*, 1998; Gilbert *et al.*, 2002), the biosynthetic pathway of ecdysteroids is still not understood completely. Biochemical approaches focusing on the nature of ecdysteroid synthetic intermediates have long formed the bulk of the results. However, unlike vertebrate steroidogenesis, where all the metabolites between cholesterol and the various active steroid hormones have been isolated and identified, no intermediate between the initial dehydrogenation product of cholesterol (7-dehydrocholesterol, 7dC) and the first recognizable ecdysteroid-like product, the 5β-ketodiol (2,22,25-trideoxyecdysone, 2,22,25dE) has ever been observed, much less identified. These are the reactions that comprise the mysterious "black box" of Dennis Horn (**Figure 11**). During invertebrate steroidogenesis, biosynthetic intermediates do not accumulate, perhaps because the proposed multistep oxidations of 7dC are either very efficient or the resulting compounds are very unstable, or both. A great step towards elucidating the synthetic mechanism in the insect was made when it was finally determined that the actual secreted product of lepidopteran prothoracic glands (Warren *et al.*, 1988a, 1988b; Sakurai *et al.*, 1989; Kiriishi *et al.*, 1990) and of most other insect prothoracic glands and crustacean Y-organs (Spaziani *et al.*, 1989; Böcking *et al.*, 1994) (see **Chapter 3.16**) was in fact not E but 3-dehydroecdysone (3DE). This finding greatly strengthened existing proposals of the early intermediacy of a 3-dehydro-Δ^4-sterol in arthropod ecdysteroidogenesis (Davies *et al.*, 1981; Rees, 1985; Grieneisen *et al.*, 1991), as it is a rather common moiety in mammalian steroidogenesis (Brown, 1998). However, the precise step at which the 3β-hydroxyl groups of early sterol ecdysteroid precursors become oxidized (dehydrogenated) to the ketone remains mystery. The recent molecular identification in *Drosophila* of the cytochrome P450 enzymes (CYP) catalyzing the terminal hydroxylation reactions at C_{25}, C_{22}, C_2, and C_{20} has provided new tools for studying these unresolved questions in ecdysteroid biosynthesis (see Section 3.3.4.3.1).

3.3.4.2.1. Cholesterol 7,8-dehydrogenation Early feeding studies showed that 7dC could support insect growth in the absence of C or phytosterols, suggesting that this compound was an early intermediate in ecdysteroid biosynthesis (Horn and Bergamasco, 1985). Subsequent kinetic studies revealed that 7dC (**Figure 11**) was the first intermediate in the formation of either E or 3DE from C, both in insects and crustaceans (Milner *et al.*, 1986; Warren *et al.*, 1988a; Grieneisen *et al.*, 1991, 1993; Rudolph *et al.*, 1992; Böcking *et al.*, 1993, 1994; Warren and Gilbert, 1996). Based on labeling experiments with radioactive precursors, the mechanism of cholesterol 7,8-dehydrogenation is known to involve the stereospecific removal of the 7β- and 8β-hydrogens from the more sterically hindered "top" (β-surface) of the planar C molecule (Rees, 1985). In several arthropod species, it was shown that the reaction is basically irreversible (Grieneisen, 1994) and is catalyzed by a microsomal CYP enzyme. This assumption was based on its biochemical characteristics, such as enzyme kinetics, subcellular localization, requirement for NADPH, or inhibition by CO and fenarimol (Grieneisen *et al.*, 1991, 1993; Warren and Gilbert, 1996).

Although its activity may become substrate limited, the cholesterol 7,8-dehydrogenase does not appear to be the rate-limiting enzyme in the biosynthesis of ecdysteroids. In many insect species, including *Manduca* (Warren *et al.*, 1988a; Grieneisen *et al.*, 1991) and *Bombyx* (Sakurai *et al.*, 1986), the

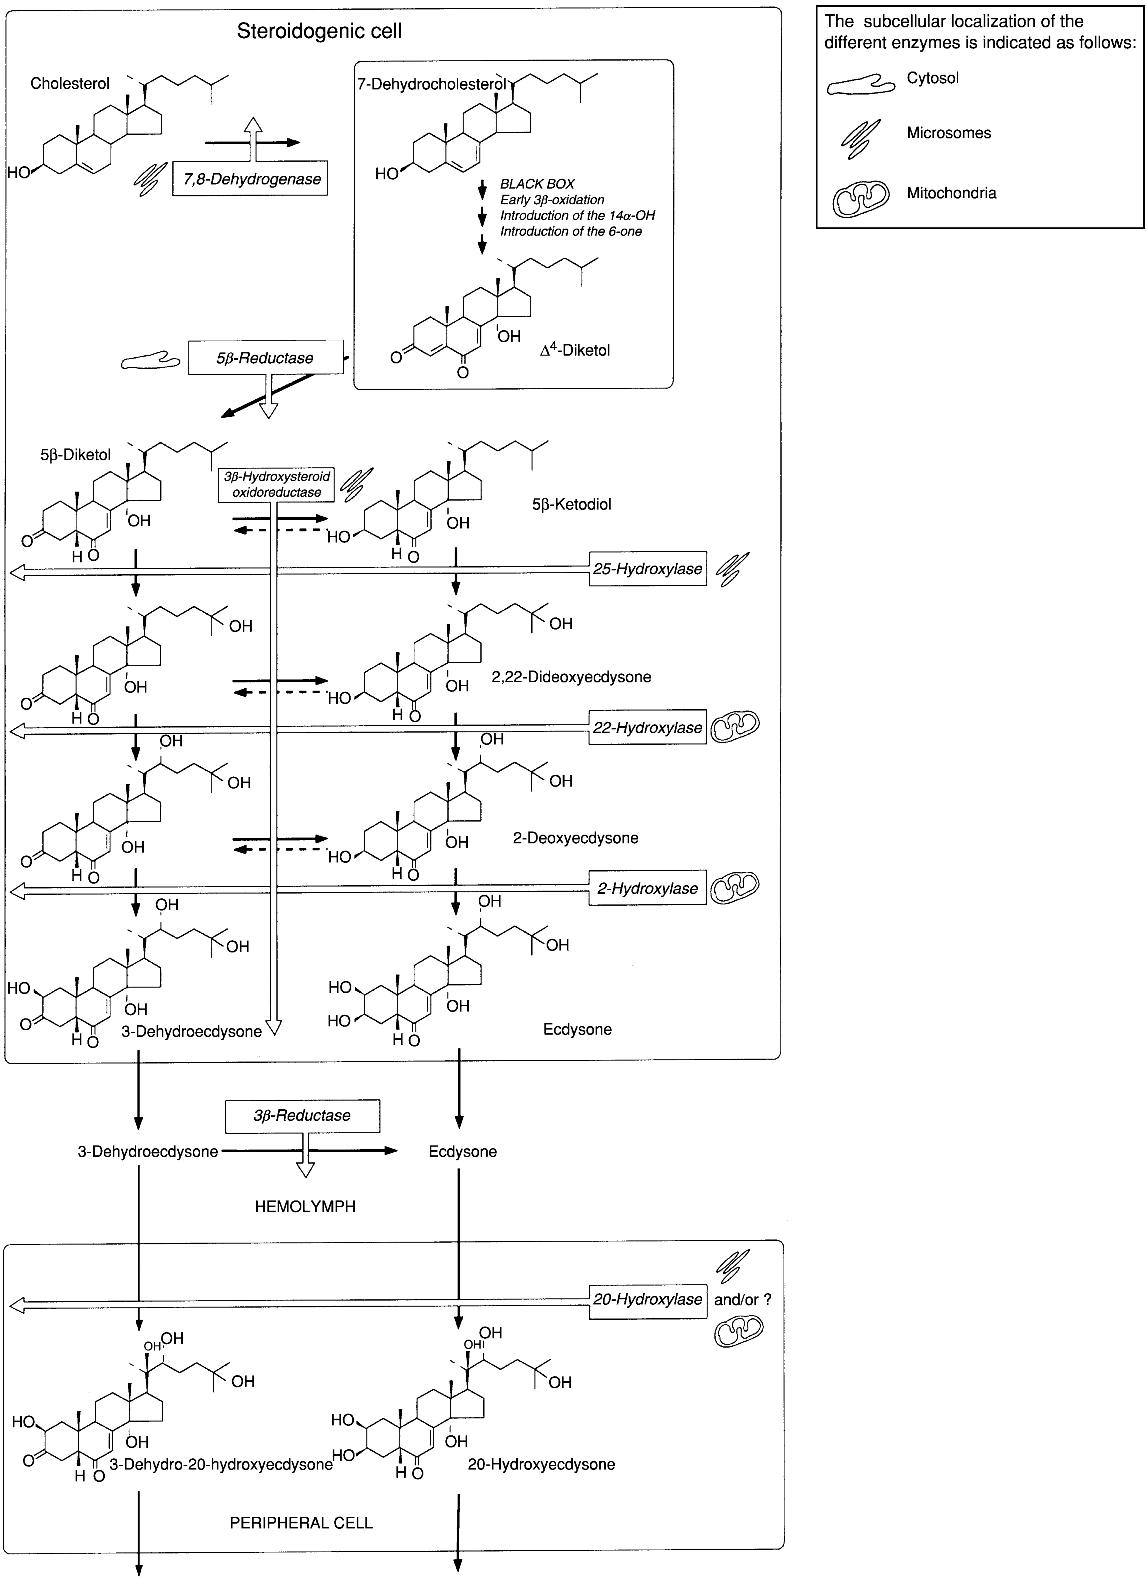

Figure 11 Putative biosynthetic pathway of ecdysteroids.

prothoracic glands always contain considerable amounts of both C and 7dC, even though both sterols undergo wild contralateral fluctuations during E biosynthesis, while in a few insect species, i.e., *Tribolium confusum, Atta cephalotes,* and *Acromyrmex octospinosus*, there is a clear preponderance of $\Delta^{5,7}$ sterols in the whole body (Grieneisen, 1994). In crabs, a ratio of 7dC:C ranging from 1:20 to 1:100 in the hemolymph was observed, while in the molting glands, the ratio was closer to 1:1 (Lachaise *et al*., 1989; Rudolph *et al*., 1992).

In the desert fly, *D. pachea*, the 7,8-dehydrogenase reaction is completely absent (Warren *et al*., 2001) and so it depends on an alternative source of 7dC. It lives on a single species of cactus that supplies it with the Δ^7-sterol lathosterol, which it alternatively dehydrogenates to 7dC (Goodnight and Kircher, 1971), i.e., similar to the synthesis of 7dC in vertebrates (Brown, 1998). Like *D. pachea*, the "low E" *Drosophila* mutant, *woc,* also shows an impairment of 7,8-dehydrogenase activity (Warren *et al*., 2001). However, in *woc*, while late third instar larval ecdysteroid production and subsequent larval–pupal metamorphosis can be rescued by the simple feeding of 7dC, continued normal development, as in *D. pachea*, is not observed in *woc* as the animals die as early pupae (see Section 3.3.5.4.3).

The 7,8-dehydrogenation of sterols appears not to have strict substrate requirements in arthropods. Cholesterol, along with the primary phytosterols campesterol, sitosterol, and stigmasterol (Sakurai *et al*., 1986), as well as the more polar synthetic substrate, 25-hydroxycholesterol (25C) (Böcking *et al*., 1994; Warren and Gilbert, 1996; Warren *et al*., 1996, 1999, 2001), are all efficiently converted into their respective 7-dehydro derivatives, both *in vivo* and *in vitro*. This is also the case for the unusual oxysterols α-5,6-epoxycholesterol (αepoC) and α-5,6-iminocholesterol, but not for their respective β-isomers (which, nevertheless, do function as competitive inhibitors of this reaction; (Warren *et al*., 1995). Only the former substrates were efficiently converted into either α-5,6-epoxy7dC, an oft-mentioned prospective "black box" intermediate (Rees, 1985) and a potentially potent alkylating agent (Nashed *et al*., 1986), or α-5,6-imino7dC, respectively. Indeed, a 46 kDa protein became increasingly radiolabeled following the incubation of ^{3}H-αepoC with *Manduca* prothoracic gland microsomes. Unfortunately, the resultant tagged product–enzyme adduct has so far proved too unstable for a classical purification and sequencing of the cytochrome. Nevertheless, the substrate specificity of the CYP enzyme for the α-isomer over the β-isomer again suggests a mechanism involving an attack by the cytochrome on the β-face of the molecule.

Even if the precise mechanism of action of the enzyme, as well as its structural characteristics, are not yet known, many studies have shown that CYPs can catalyze a great diversity of reactions, including dehydrogenation reactions. In vertebrates, for instance, dehydrogenation of the alkane CH-CH bond from testosterone is catalyzed by a CYP. The P450-dependent oxidation of this substrate not only leads to a dehydrogenated metabolite, but also to a hydroxylated metabolite, the latter not being a metabolite of the former (Mansuy, 1998). A similar mechanism might be envisioned for cholesterol 7,8-dehydrogenation, although the formation of such a hydroxylated C derivative has not been observed in insects. Nevertheless, one such possible intermediate (7β-hydroxycholesterol) did significantly inhibit the conversion of radiolabeled C to either 7dC or E (Grieneisen *et al*., 1991), but precise chemical studies are needed with a recombinant enzyme when it becomes available.

3.3.4.2.2. Early steps after the formation of 7dC: the "black box" Conversion of 7dC to the 5β-ketodiol or 5β-diketol, via the long-hypothesized 3-dehydro-Δ^4-diketol (cholesta-4,7-diene-3,6-dione-14α-ol) intermediate, constitutes the so-called "black box" (**Figure 11**). The name is most apt, as both the mechanism of this apparent multistep oxidation, as well as the subcellular location of all these reactions, is still a matter of great debate. Several modifications of 7dC appear to take place early and seemingly simultaneously, i.e., oxidation of the 3β-alcohol to the ketone (with stereospecific loss of the 3α-hydrogen), C_6 oxidation with additional loss of the 4β- and 6-hydrogens and formation of the 6-keto group, and finally 14α-hydroxylation. These observations are consistent with the intermediacy of 3-dehydro-Δ^4-diketol (Davies *et al*., 1981; Rees, 1985; Grieneisen *et al*., 1991; Dauphin-Villemant *et al*., 1998). Analogous to the rate-limiting step in mammalian steroidogenesis, it has long been thought that most or all of these reactions take place in the mitochondria and may be catalyzed by one or more P450 enzymes. That is, 7dC (or 7-dehydro25C) could not be converted into ecdysteroids by the crude microsomal fraction, only by the crude mitochondrial fraction of *Manduca* prothoracic glands. However, as no intermediates could be detected, no reaction mechanism was apparent (Grieneisen *et al*., 1993; Warren and Gilbert, 1996).

Nevertheless, some "negative" evidence has been obtained from metabolic studies concerning these

early biochemical modifications. Concerning 14α-hydroxylation, the results of incubations of *Manduca* prothoracic glands (Bollenbacher *et al.*, 1977a) or *Locusta migratoria* prothoracic glands or ovaries (Haag *et al.*, 1987) have suggested that this reaction must take place before, or in concert with, the introduction of the 6-keto group. That is, 3β-hydroxy-5β-cholest-7-en-6-one can be efficiently converted to 14-deoxy-ecdysone, but not to E.

Several hypotheses have also been tested concerning the introduction of the 6-keto group. Even though 6-hydroxyl-sterol derivatives have been isolated in some biological models, ecdysteroid analogs with a 6-hydroxyl group could not be oxidized to form true ecdysteroids with a 6-ketone group (Schwab and Hétru, 1991; Grieneisen, 1994; Gilbert *et al.*, 2002). The possibility that either a 3-dehydro-α-5,6-epoxy-7dC molecule (Grieneisen *et al.*, 1991; Warren *et al.*, 1995) or a 3-dehydro-5α,8α-epidioxide (J. Warren, C. Dauphin-Villemant, and R. Lafont, unpublished data) could be converted to a 3-dehydro-Δ^4-sterol intermediate has also been investigated. However, when incubated with prothoracic glands from insects or Y-organs from crustaceans, these compounds (either nonradioactive or as radioactive tracers) were never shown to be converted into known ecdysteroids (Gilbert *et al.*, 2002).

Finally, if the 3-dehydro-Δ^4-diketol (**Figure 11**) is an intermediate in ecdysteroid biosynthesis, its formation would also require an early oxidation step at C_3. However, as yet, every attempt to understand when and how this step takes place has failed. In studies with either prothoracic glands or Y-organs, the early oxidation of C (or 25C) to 3-dehydro-C (or 3-dehydro-25C) has never been directly observed. The facile conversion of these oxidized sterols, by either acid or base catalysis, to their distinctive isomerization products, 3-dehydro-Δ^4-C or 3-dehydro-Δ^4-25C, has also never been detected in vivo or in vitro (J. Warren and R. Lafont, unpublished data). Due to greater electron delocalization, 3-dehydro-7dC is very much more unstable, instantly converting into its more stable 3-dehydro-$\Delta^{4,7}$ sterol isomer when placed in an aqueous environment (Antonucci *et al.*, 1951; Lakeman *et al.*, 1967). However, the formation of either of these compounds (or their 25C analogues) has never been observed during ecdysteroid biosynthesis from radiolabeled precursors. Apparently, C_3 oxidation most likely occurs in concert with subsequent oxidations of these very unstable intermediates.

A hypothesis where all three modifications might possibly be performed simultaneously by a single enzyme (perhaps a CYP enzyme localized in the mitochondria) has been proposed (Gilbert *et al.*, 2002). However, at present, mitochondrial CYP involvement in these hypothetical black box oxidations is not supported for *Drosophila*. All six families of putative mitochondrial CYPs have been tentatively identified on the basis of their conserved motifs associated with the specific cofactor (adrenodoxin) binding to the cytochrome (Tijet *et al.*, 2001) (see **Chapter 4.1**). According to tissue expression studies in *Drosophila* (C. Dauphin-Villemant and M. O'Connor, unpublished data), no mitochondrial CYP has been localized to the ring glands, other than those already identified as catalyzing the final 2- and 22-hydroxylation steps (see Section 3.3.4.3.1). Nevertheless, even if the black box reactions do not involve mitochondrial P450 enzymes, these oxidation reactions could still occur in the mitochondria. Alternatively, it remains a possibility that these reactions are instead localized within an alternative membrane-bound subcellular organelle, that is, either another domain of the endoplasmic reticulum (ER) or an organelle known to be involved in the oxidation of numerous substrates (including some mammalian sterols), i.e., the peroxisome (see Section 3.3.6.2). In any case, regardless of the location and mechanisms of the black box reactions, they appear to be quite novel and so may be specific to many invertebrates.

3.3.4.2.3. Reduction steps of a proposed 3-dehydro-Δ^4-ecdysteroid intermediate Even though there is as yet no direct evidence for the intermediacy of the 3-dehydro-Δ^4-diketol in the biosynthesis of ecdysteroids, it still remains a good candidate. This is substantiated by several lines of evidence. It has been shown to be efficiently converted first to the 5β-diketol (and subsequently to 3DE and E) by a 5β-reductase present primarily in the Y-organs of crustaceans, i.e., in the crab *Carcinus maenas* (Blais *et al.*, 1996) and the crayfish *Orconectes limosus* (C. Blais, C. Dauphin-Villemant, and R. Lafont, unpublished data). The reaction is quite specific for the correct oxidation state of the substrate at C_3, as no reduction of the unoxidized 3β-OH-Δ^4-sterol intermediate was observed either in crab Y-organs (Blais *et al.*, 1996) or in insect prothoracic glands (Bollenbacher *et al.*, 1979). However, the complete characterization of an arthropod 3-dehydro-Δ^4-steroid 5β-reductase is still lacking as all attempts to demonstrate a similar reaction in insects have so far been unsuccessful. Nevertheless, in all other vertebrates or plants investigated so far, the formation of 5β[H]-cholesterol derivatives always proceeds through such 3-dehydro-Δ^4-sterol intermediates (Brown, 1998).

In the case of species producing only 3β-hydroxylated ecdysteroids, i.e., E or 20-deoxymakisterone A or C, the postulated intermediacy of the 3-dehydro-Δ^4-diketol and diketol in the biosynthetic pathway implies the presence of a 3β-reduction step involving subterminal compounds in the molting glands (**Figure 11**). Until now, the interconversion between 3-dehydro and 3-OH compounds has essentially been documented only in the hemolymph and peripheral tissues of several arthropods (see Section 3.3.5.3.2). A cytosolic NADPH requiring enzyme has been identified. It is able to rapidly and irreversibly catalyze the conversion of 3DE into E, which, in turn, is rapidly hydroxylated to 20E. This enzyme has been cloned in the lepidopterans *Spodoptera littoralis* (Chen *et al*., 1999b) and *Trichoplusia ni* (Lundström *et al*., 2002). However, this enzyme cannot be responsible for 3β-reduction in the prothoracic glands, since it retains a rather narrow substrate specificity, is unable to reduce subterminal intermediates of ecdysteroidogenesis, and, furthermore, is not expressed in the steroidogenic tissues.

However, in the crab, *Carcinus maenas*, a microsomal enzyme similar to the 3β-hydroxysteroid dehydrogenase (3βHSD) from vertebrates has been detected specifically in the Y-organs (Dauphin-Villemant *et al*., 1997). In the presence of NADH, it can catalyze the 3β-reduction not only of the diketol, but also 3-dehydro-2,22-dideoxyecdysone and 3-dehydro-2-deoxyecdysone, but not 3DE. Interestingly, in the presence of NAD^+, the same subcellular fraction can re-oxidize 2-deoxyecdysone and 2,22-deoxyecdysone back to the original 3-dehydro substrates, suggesting a reversible reaction consistent with a true 3βHSD activity.

3.3.4.2.4. Late hydroxylation steps Starting from either the 5β-diketol or 5β-ketodiol (the terminal 3-dehydro or 3-OH products of the black box), conversion initially into 3DE or E and ultimately into 3D20E or 20E (**Figure 11**) is well documented. The 5β-ketodiol appears to be a true intermediate in ecdysteroid biosynthesis since at least in one insect species, *Locusta migratoria,* it has been identified as an endogenous compound of ovaries, in addition to 7dC (Hétru *et al*., 1978, 1982). It was also identified as a conversion product from [^{3}H]-cholesterol during *in vitro* incubations of ovaries (Hétru *et al*., 1982) and following [^{3}H]-cholesterol injections into nondiapause eggs of *B. mori* (Sonobe *et al*., 1999). Furthermore, it has been demonstrated in several insect and crustacean species (Grieneisen, 1994) that both prothoracic glands and Y-organs are able to convert the 5β-ketodiol very efficiently into E via sequential hydroxylations at C_{25}, C_{22}, and C_2 (**Figure 11**). Subsequent hydroxylation of circulating E at C_{20}, catalyzed by an ecdysone 20-monooxygenase present in peripheral tissues, yields the active molting hormone 20E (see Section 3.3.5.2).

It has long been accepted that the enzymes catalyzing these reactions are four different monooxygenases belonging to the CYP superfamily (see **Chapter 4.1**), based on their biochemical characteristics, i.e., membrane subcellular localization, NADPH cofactor, and O_2 requirement and inhibition of the reaction by CO or by classical CYP inhibitors like fenarimol, metyrapone, or piperonyl butoxide observed in various arthropods (Grieneisen, 1994). In this respect, the 2-hydroxylase presents some peculiar features, since it is insensitive to CO and apparently can function with some Krebs cycle intermediates (succinate or isocitrate) in addition to NADPH (Kappler *et al*., 1986, 1988).

The subcellular distribution of these terminal hydroxylases has been studied in several arthropod models. While the tissue locations of the enzymatic activities of the first three enzymes in insects (Kappler *et al*., 1988; Grieneisen *et al*., 1993) and crustaceans (Blais *et al*., 1996; Dauphin-Villemant *et al*., 1997) are not clear-cut, it is nevertheless widely accepted that the 25-hydroxylase is a microsomal enzyme whereas the 2- and 22-hydroxylases are strictly mitochondrial. In contrast, the 20-hydroxylase has been shown to be microsomal, mitochondrial, or, in some instances, both (Bollenbacher *et al*., 1977b; Feyereisen and Durst, 1978; Smith *et al*., 1979; Smith, 1985; Mitchell and Smith, 1986; Smith and Mitchell, 1986; see Section 3.3.5.2). The subcellular localization of all these CYP enzymes has now been directly demonstrated in *Drosophila* S2 cells (see Section 3.3.4.3.1).

By analogy with steroid hormone biosynthesis in vertebrates, the identified hydroxylases might be expected to be expressed specifically in the endocrine tissues (or peripheral tissues for the 20-monooxygenase) and perhaps act through a preferential sequence of hydroxylations. Yet, early metabolic studies (Rees, 1985) have reported 2-, 22-, and 25-hydroxylase activities in a number of tissues, not only larval prothoracic glands and adult ovaries, but also in fat body, Malpighian tubules, gut, and epidermis. However, the specific activity of the observed enzymatic activities was seldom mentioned and a closer examination always revealed a substrate conversion that was much more efficient in true steroidogenic organs (prothoracic glands, Y-organs, ovaries) than in other tissues, at least in terms of the C_{22}- and C_{25}-hydroxylations (Meister *et al*., 1985; Rees, 1985, 1995; Grieneisen, 1994). While the

evidence for C_2-hydroxylation activity outside the ring gland remains strong, the C_{25} and C_{22} activities may have been due to the use of crude preparations with the possibility that other CYPs where present in the subcellular fractions. Cytochromes with broader substrate specificities (detoxification enzymes, for instance) may, to some extent, have been able to convert intermediates into ecdysteroids.

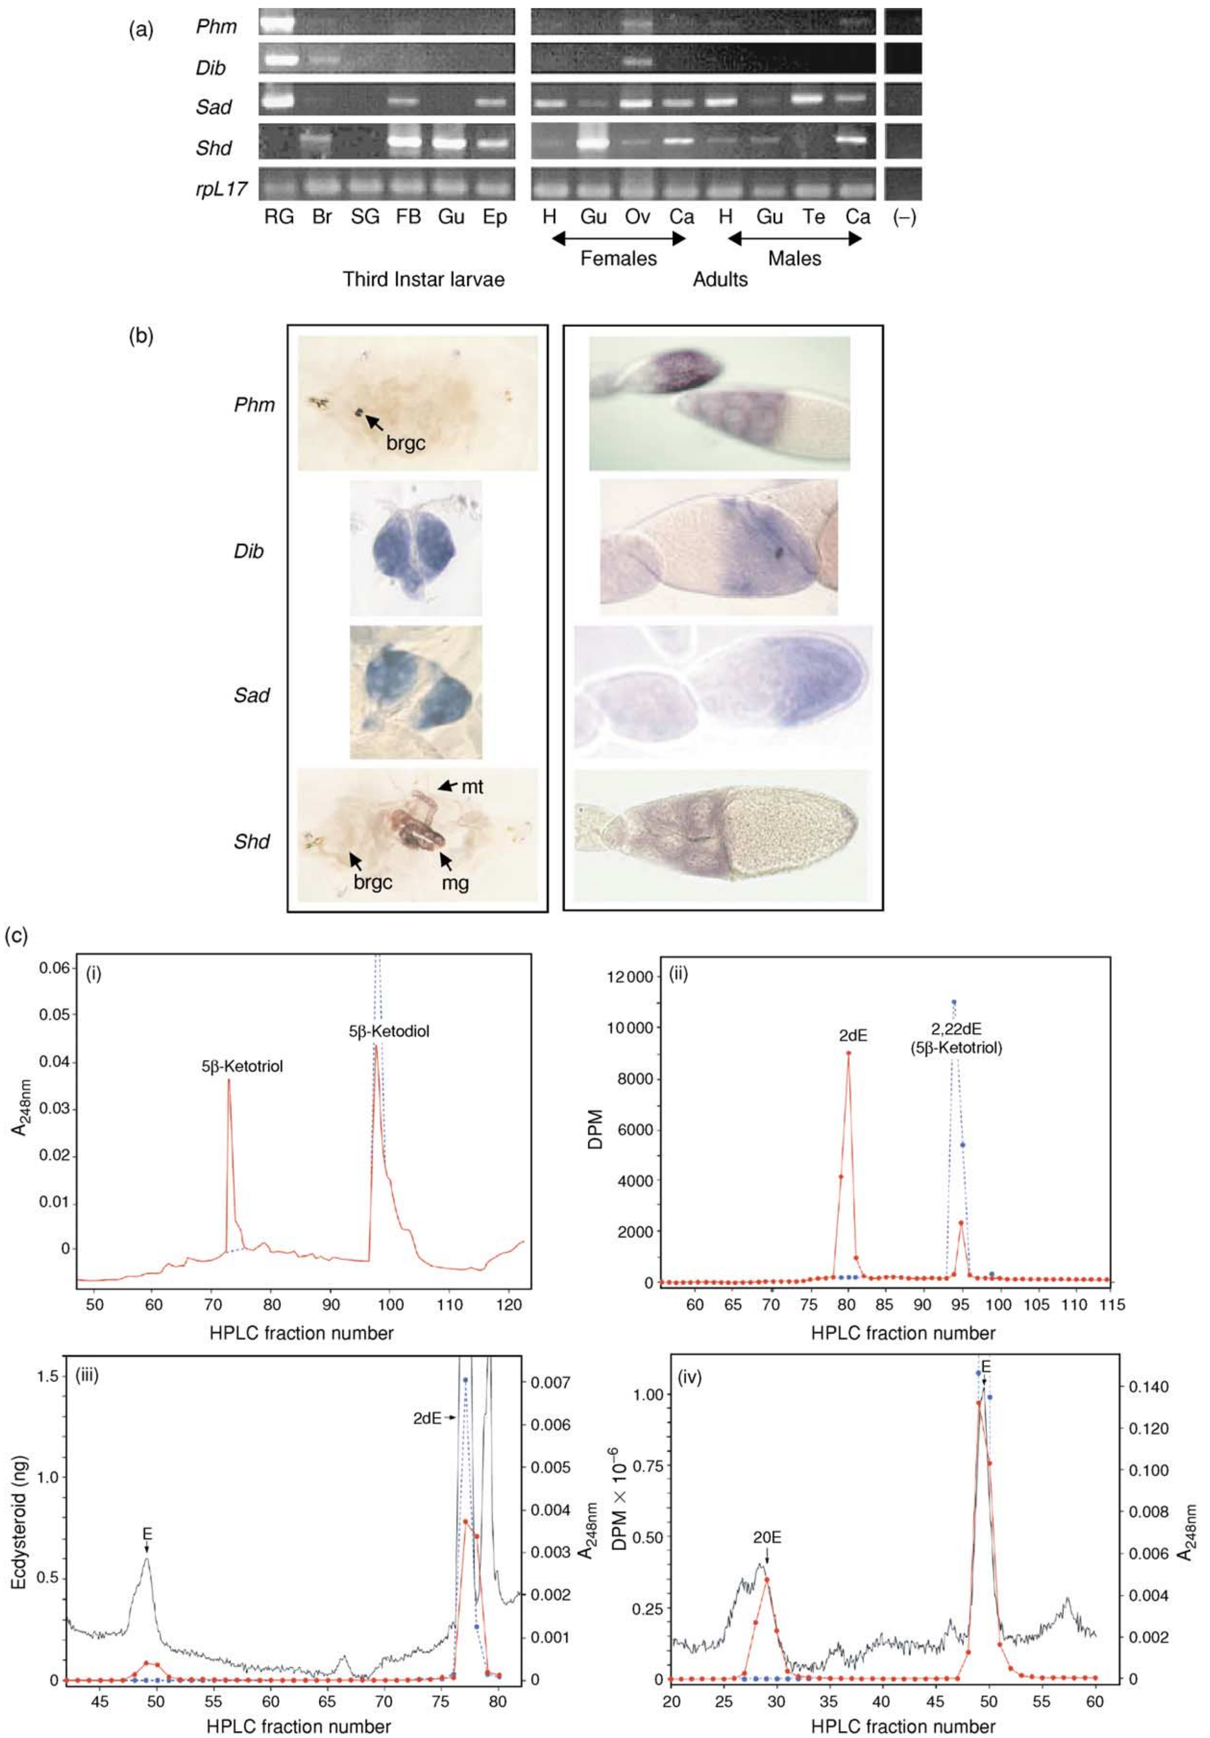
Another characteristic of the enzymes involved in vertebrate steroidogenesis is that the reactions generally occur in a preferred sequence, both due to their precise substrate specificities and their subcellular compartmentalization (Brown, 1998). This appears to be at least partly true in the case of ecdysteroid biosynthesis, even though additional enzymological studies are necessary. In fact, accumulation of many intermediates has been repeatedly reported in insect and crustacean systems when using labeled 5β-ketodiol as an exogenous precursor (Rees, 1985; Grieneisen, 1994). However, these compounds have not been identified as endogenous intermediates and might therefore be artifacts. More precisely, if hydroxylation at C_2 occurs first in either the 5β-ketodiol (2,22,25dE) or ketotriol (2,22dE), it leads to a dead end. This has been shown both in insects (Dollé *et al*., 1991; Rees, 1995) and crustaceans (Lachaise *et al*., 1989; Pís *et al*., 1995b) since both 22,25-dideoxyecdysone and 22-deoxyecdysone (Warren *et al*., 2002) are only poorly converted into E via hydroxylation at C_{22}. On the other hand, C_{25}-hydroxylation does not appear to be the last biosynthetic step, since 25-deoxyecdysone is a major secretory product in several crab species (Lachaise *et al*., 1989; Rudolph and Spaziani, 1992), but has not been found in insects. Taken together, these results suggest that the last steps in E biosynthesis within the endocrine gland also follow a preferential sequence of hydroxylations.

The present hypothesis suggests that the first terminal oxidation reaction of the newly reduced black box product (i.e., the 3-dehydro-Δ^4-diketol), whether localized in the mitochondria, ER, the peroxisome, or in the cytosol around these organelles, nevertheless occurs at C_{25} within the ER. Then, after translocation of the resulting 5β-ketotriol product to the mitochondria, sequential hydroxylations take place, the first necessarily at C_{22} and the last at C_2, followed by the secretion of the product from the cell as either 3DE and/or E. Circulating E is then converted to 20E in the peripheral tissues. Thus, in arthropods, the apparent preferential sequence of biosynthetic steps may be due more to their particular subcellular compartmentalization than to any strict substrate specificity. That is, the more convenient access of this cytosolic substrate to the 25-hydroxylase in the ubiquitous ER may determine the first reaction. Curiously, of the last two mitochondrial enzymes, the 22-hydroxylase apparently must function first, as the formation of the alternative 2-hydroxylated product (22dE), while not prohibited by any strict substrate specificity, nevertheless is not normally observed *in vivo*. Specific compartmentalization of these two enzymes within the mitochondria may somehow restrict initial substrate (2,22dE) access to the 2-hydroxylase.

3.3.4.2.5. Various secretion products: single or multiple metabolic pathways? Ecdysteroid biosynthesis has been studied in various model systems, i.e., steroidogenic tissues originating from animals producing different and sometimes exclusive ecdysteroids. There is a general implicit postulate that production of the same ecdysteroid proceeds through a common pathway in all investigated arthropods. This means that orthologous enzymes are expected to be identified in the various species. Until now, however, comparative structural data has been lacking. On the other hand, the occurrence of different secretory products in different species raises the question of whether they are the result of profound changes in ecdysteroid biosynthesis or just the effect of minor differences in pathways. The reason for the different oxidation state at C_3 in the two major ecdysteroid products identified in many arthropod species, i.e., E or 3DE, might involve just variability in the activity or expression of a terminal reductase in or near the steroidogenic tissue. Such a hypothesis is substantiated by the fact that, generally, in 3DE-producing species, the conversion of the 5β-diketol leads preferentially to 3DE, while the conversion of the 5β-ketodiol is also efficient but leads to E (Böcking *et al*., 1993; Grieneisen, 1994). Similarly, the preferential production of 25-deoxy ecdysteroids by crab Y-organs may be due simply to the absence or the very low expression of the 25-hydroxylase in crustaceans. However, the mechanisms for these differences may be more complex and could involve different substrate specificities of the corresponding enzymes.

3.3.4.3. Molecular Analysis of Ecdysteroid Biosynthesis

Different approaches have been engaged in recent years in order to gain structural information about the genes and proteins involved in ecdysteroid biosynthesis. With regard to the biosynthetic enzymes, a first approach has been to take advantage of expected sequence homologies and look for CYP enzymes expressed specifically in prothoracic glands (Snyder *et al*., 1996). Using this strategy, CYP



enzymes specific to *Manduca* prothoracic glands (see **Chapter 4.1**) and crayfish (*Orconectes limosus*) Y-organs (Dauphin-Villemant *et al.*, 1997, 1999) were identified. Curiously, both were of the CYP4 family, but their precise function has not yet been elucidated.

In *Drosophila*, genetic approaches as well as the recent sequencing of the genome represent powerful tools to identify genes involved in ecdysteroid biosynthesis. Several mutations, including *ecdysoneless* (*ecd*[1]), *DTS3, dre4, giant*, and *woc*, have been shown to affect E titers (Garen *et al.*, 1977; Walker *et al.*, 1987; Schwartz *et al.*, 1984; Sliter and Gilbert, 1992; Warren *et al.*, 1996; Wismar *et al.*, 2000) and consequently development and metamorphosis. However, the corresponding genes appear to be more linked either to the transcriptional regulation of ecdysteroid production or to the efficient delivery of ecdysteroid intermediates to the enzymatic machinery rather than to the biosynthetic enzymes themselves. For instance, *giant* encodes a bZIP (basic-leucine zipper) transcription factor (Capovilla *et al.*, 1992), *ecd*[1] may impair sterol availability (Warren *et al.*, 1996) while *woc* encodes a transcription factor with eight zinc fingers (Wismar *et al.*, 2000) that appears (in the least) to regulate expression of the cholesterol 7,8-dehydrogenase (Warren *et al.*, 2001). An enhancer-trap approach has also been used in recent years (Harvie *et al.*, 1998) in order to begin characterizing the function of *Drosophila* ring glands during larval development. Several genes have been identified as specifically expressed in the lateral cells of the ring gland (i.e., the prothoracic gland cells), but there is presently no evidence that they are involved in ecdysteroid biosynthesis.

3.3.4.3.1. Identification of steroidogenic cytochrome P450 enzymes While many of the early oxidation steps in ecdysteroid biosynthesis are still incompletely understood, it nevertheless appears to involve a cascade of sequential hydroxylations catalyzed by several cytochrome P450 enzymes. A combination of molecular genetics and biochemistry was used recently to further elucidate these reactions in the biosynthetic pathway in *Drosophila*. One phenotype predicted for mutations that disrupt the production of ecdysteroids would be the inability to produce a cuticle at any stage, the earliest being the synthesis of embryonic cuticle during the second half of embryogenesis. Among the mutants screened by Nüsslein-Volhard and colleagues in their landmark characterization of embryonic patterning (Jürgens *et al.*, 1984; Nüsslein-Volhard *et al.*, 1984; Wieschaus *et al.*, 1984), several were later grouped under the name of the *Halloween* mutants (Chavez *et al.*, 2000). They were selected for their similar abnormal cuticular patterning and low ecdysteroid titers, suggestive of a defect in the ecdysteroid pathway. In all of them, several developmental and physiological defects (i.e., absence of head involution, dorsal closure, and gut development) were associated with a very poor differentiation of embryonic cuticle and which led to lethality before the end of embryonic development.

While the first Halloween gene, *disembodied* (*dib*) (CYP302A1) was located by classical molecular techniques (Chavez *et al.*, 2000), in order to select the remaining genes, the *Drosophila* genome was searched for the presence of cytochrome P450 enzyme-type sequences near the known map location of these genes. At least four other genes, *phantom (phm), spook (spo), shadow (sad)*, and *shade (shd)* were shown to also code for CYP enzymes, CYP 306A1, CYP307A1, CYP315A1, and CYP314A1, respectively (Warren *et al.*, 2002; Petryk *et al.*, 2003; Warren *et al.*, 2004), as they retained the conserved domains characteristic of this superfamily (particularly the high conservation of the heme-binding domain at the C-terminal end). Owing to a high divergence in their overall sequence as compared to other already known sequences, these enzymes are members of a new CYP family (see drnelson for nomenclature) (see **Chapter 4.1**). Four of them, *phm*, *sad*, *dib*, and *shd*, have now been fully characterized, as their corresponding enzymes, when expressed in *Drosophila* S2 cells, have been shown to catalyze the last four reactions in ecdysteroid biosynthesis, i.e., the terminal 25-, 22-, 2-, and 20-hydroxylations (see below).

Dib and *sad* mRNAs are initially expressed in the epidermis during early embryogenesis and then later in classical steroidogenic tissues, i.e., in ring glands from late embryogenesis to metamorphosis and in the nurse and/or follicle cells of adult female ovaries. Their expression patterns were studied using *in situ* hybridization on different tissues in addition to RT-PCR analysis (**Figure 12 a** and **b**). More recently, it was shown that *phm* retains an almost identical expression pattern to *dib* (Warren *et al.*, 2004), while *sad* actually exhibits a much broader pattern, consistent with prior tissue activity studies, including not only expression in the steroidogenic tissues (Warren *et al.*, 2002), but also significant expression in the gut and epidermis in larvae and adults (**Figure 12 a** and **b**). In contrast, while *shd* is also expressed in the early embryonic epidermis, it is not expressed in late embryonic or larval ring glands, but instead is prominent in peripheral larval tissues and adult ovaries (Petryk *et al.*, 2003).

The initial hypothesis that *dib* and the other Halloween gene CYPs might catalyze steps in the ecdysteroid biosynthetic pathway has now been confirmed by the biochemical characterization of the Phm, Dib, Sad, and Shd CYP enzymes. The cDNA coding sequences of these genes have been transiently transfected into *Drosophila* S2 cells as expression plasmids under the control of the actin 5C promoter. When the transfected cells are incubated with specific ecdysteroid precursor substrates, they efficiently and selectively convert them to product (**Figure 12c**), indicating the 25-, 22-, 2-, and 20-hydroxylase functions for Phm, Dib, Sad, and Shd respectively. Additional information on the substrate specificities of these enzymes was obtained in a similar manner. For instance, *dib*-transfected cells converted 2,22-dideoxyecdysone (the 5β-ketotriol) to 2-deoxyecdysone (**Figure 12c**), but could not convert 22-deoxyecdysone to E, confirming the strict substrate requirement (i.e., the absence of a 2-hydroxy function) for the 22-hydroxylase enzyme, at least in this expression system (Warren *et al.*, 2002). On the other hand, cells transfected with *sad* hydroxylated not only 2-deoxyecdysone and 2,22-dideoxyecdysone at C_2 (Warren *et al.*, 2002), but also 2,22-dideoxy-20-hydroxyecdysone (C. Blais, C. Dauphin-Villemant, and R. Lafont, unpublished data), suggesting that modifications on the side chain do not necessarily interfere with the active site of this enzyme. Similarly, cells transfected with *phm* converted not only 2,22,25-trideoxyecdysone (the 3β,5β-ketodiol) to 2,22-dideoxyecdysone, but also 25-hydroxylated both the 3β,5α-ketodiol and the 3α,5α-ketodiol to their respective isomeric ketotriol products (Warren *et al.*, 2004)). Apparently, in this case, A/B-ring and C_3 stereochemistry are relatively unimportant determinants for Phm activity. However, Phm could not metabolize 25dE to E or ponasterone A to 20E, indicating an inability (as was observed with Dib) to recognize substrates prematurely hydroxylated at C_2. Detailed enzymological and mechanistic studies are now possible following the stable, heterologous expression in nonsteroidogenic cell lines of both single and multiple (i.e., linked) steroidogenic P450 enzymes targeted to either the mitochondria or the endoplasmic reticulum, or both.

Cytochrome P450 enzymes, as membrane-bound enzymes, have so far been found to be either localized in the endoplasmic reticulum or in the mitochondria of eukaryotes (see **Chapter 4.1**). Their amino acid sequences at the N-terminus present conserved structural features that are hypothesized to direct their subcellular localization (Omura and Ito, 1991; Von Wachenfeldt and Johnson, 1995; Van den Broek *et al.*, 1996) (see **Chapter 4.1**). The N-terminal sequences deduced from *dib* and *sad* cDNAs (**Figure 13**) are consistent with their mitochondrial localization previously determined for the C_2- and C_{22}-hydroxylases from subcellular fractionation studies in *Locusta* (Kappler *et al.*, 1986, 1988) and *Manduca* (Grieneisen *et al.*, 1993). Both contain numerous positively charged residues, in addition to many polar groups within the first 20–30 amino acids. In contrast, the N-terminus of Shd (the 20-monooxygenase) and Spo (which remains

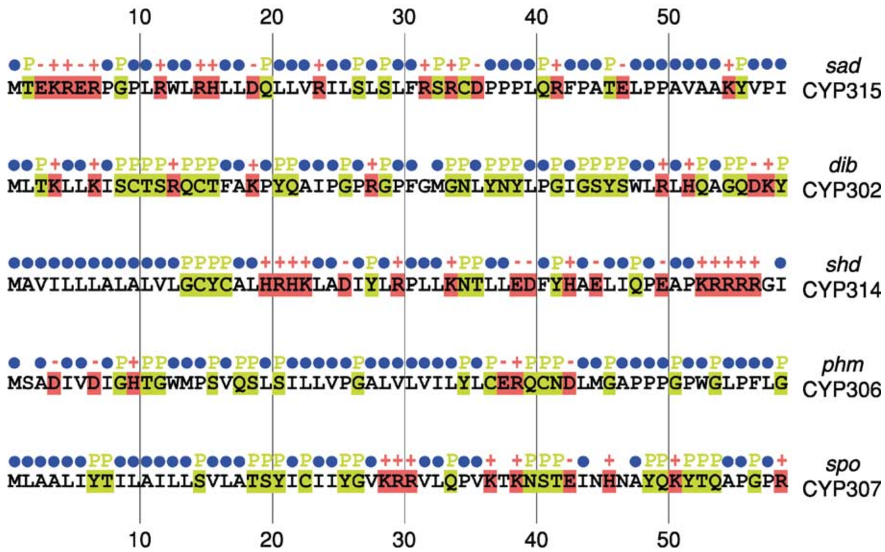

Figure 13 Predicted N-terminal amino acid sequence of the Halloween P450 genes. Red represents charged (+/−) residues, yellow shows polar (P) residues, and blue circles represent nonpolar amino acids. Prominent charged residues in the N-terminal 20–30 amino acids of P450 enzymes are thought to be involved in the targeting of the protein to the inner mitochondrial matrix. Alternatively, predominantly nonpolar N-terminal residues are thought to help anchor the protein in the membrane of the endoplasmic reticulum. unidentified) consists of a string of about 20 or more hydrophobic amino acids devoid of charged residues, suggesting that both these CYP enzymes are targeted to the endoplasmic reticulum.

The mitochondrial localization of the Dib and Sad cytochromes has been confirmed by *in situ* localization of the corresponding C-terminal, epitope-tagged (His or HA) proteins expressed in S2 cells (Warren *et al.*, 2002; Petryk *et al.*, 2003). However, in apparent contradiction of the above considerations, when a similarly tagged *shd* construct was transfected into S2 cells, it was determined that it, like *dib* and *sad*, also localized in the mitochondria and not in the ER (Petryk *et al.*, 2003). When phylogenetic trees with various CYPs are constructed, *shd* always clusters (along with *dib* and *sad*) with the mitochondrial CYPs, primarily because of shared sequences associated with binding to its redox partner adrenodoxin (Tijet *et al.*, 2001) (see **Chapter 4.1**). However, upon closer examination of the Shd N-terminus (**Figure 13**), a possible mitochondrial import sequence containing numerous charged residues is present immediately downstream from the apparent microsomal targeting sequence. Protease-mediated cleavage of the N-terminus of Shd, thereby eliminating the initial string of hydrophobic residues, could result in the retargeting of this enzyme to the mitochondria. Such differential posttranslational modification of Shd could explain the observed distribution of ecdysone 20-monoxygenase activity into either the mitochondria or ER or both, depending on the insect, tissue, or stage (see Section 3.3.5.2). A similar situation has been reported for mammalian CYP1A1, which has a chimeric N-terminal signal that facilitates the targeting of the protein to the ER and, following protease action, to the mitochondria (Addya *et al.*, 1997). Not clear, however, is how the P450 enzyme manages to interact with apparently separate reductase cofactors when it is present in these two different membrane environments (see Section 3.3.4.3.2).

The predicted N-terminal sequence of Phm (**Figure 13**) could present a similar anomaly, as there is no typical hydrophobic stretch in the first 20 amino acids. However, if one considers the second methionine at position 14 as being the real start of the protein, then the following 20 amino acids are mainly hydrophobic and so would suggest an ER import sequence. Indeed, a similarly tagged Phm

enzyme was found to localize in the ER of transfected S2 cells (Warren *et al.*, 2004), consistent with prior biochemical characterizations of the 25-hydroxylase in arthropods (Kappler *et al.*, 1988).

Several points should be noted regarding the molecular evolution of CYP genes and their relation to steroidogenesis. It is postulated that all cytochrome P450 enzymes are derived from a few ancient CYPs (Nelson, 1998) (see **Chapter 4.1**). As additional genomes are deciphered, genes putatively orthologous to *phm*, *dib*, *sad*, and *shd* will soon be identified in *Anopheles gambiae, Drosophila pseudoobscura*, and *Bombyx*. Comparative studies and rapid progress in insect genomics will allow confirmation that these orthologous genes actually catalyze the same reactions in mosquitoes and other insects as they do in *Drosophila*. Indeed, following similar heterologous expression in *Drosophila* S2 cells, it was recently determined that a *Bombyx* gene analogous to *phm* also codes for a P450 enzyme that catalyzes specific ecdysteroid 25-hydroxylation (Warren *et al.*, 2004). Furthermore, as was shown for the *Drosophila* ring gland-specific genes *dib*, *sad* and *phm* (Warren *et al.*, 2002; Petryk *et al.*, 2003; Warren *et al.*, 2004), *Bombyx phm* expression in the prothoracic gland cells during the last larval–larval molt undergoes a dramatic down-regulation by the beginning of the last larval stadium (Warren *et al.*, 2004), perhaps the result of feedback inhibition by the product, 20E, operating via its nuclear receptor (see **Chapter 3.8**).

Finally, recent advances in the knowledge of insect genomes will likely enable the identification of all the P450 enzymes involved in ecdysteroid biosynthesis (including the cholesterol 7,8-dehydrogenase) in the near future. For instance, all putative CYP genes have been identified in *Drosophila* (Tijet *et al.*, 2001) (see **Chapter 4.1**). There is no doubt that a systematic analysis of the tissue expression of all CYP genes will enable us to determine the best candidates coding for the remaining enzymes involved in ecdysteroid biosynthesis. More integrated approaches using microarray technology approaches are presently available and should constitute new tools to identify the large set of genes specifically expressed in steroidogenic cells and so potentially linked to ecdysteroidogenesis.

3.3.4.3.2. Electron transport involved in cytochrome P450 reactions (see **Chapter 4.1**) Monooxygenations catalyzed by cytochrome P450 enzymes require molecular oxygen and two electrons during their catalytic cycle. In vertebrate steroidogenesis, the electron transfer systems associated with the mitochondrial and microsomal CYP enzymes are different. In the mitochondrial system, reduction occurs with FAD as the flavoprotein (adrenodoxin reductase), which transfers electrons to an iron-sulfur protein (adrenodoxin) and finally to the CYP. In contrast, in the microsomal system, cytochrome P450 reductase, a flavoprotein containing both FMN and FAD, passes electrons directly from NADPH to the CYP. The second electron may alternatively arise from NADPH via cytochrome b_5, and a number of forms of cytochrome P450 show an obligatory requirement for cytochrome *b5* (Miller, 1988; Schenkman and Jansson, 2003).

There is some evidence in arthropods that ecdysteroid hydroxylations catalyzed by CYPs involve electron transfer systems analogous to those used in vertebrates (see **Chapter 4.1**). The obligatory function of cytochrome P450 reductase and the adrenodoxin/adrenodoxin reductase system in the function of microsomal and mitochondrial CYPs, respectively, has been indicated by immunoinhibition studies. Anti-adrenodoxin and anti-adrenodoxin reductase antibodies effectively inhibited ecdysone 20-monooxygenase activity in *Spodoptera* fat body mitochondria (Chen *et al.*, 1994a). Similarly, antibodies raised against cytochrome P450 reductase inhibited microsomal E 20-monooxygenase activity in *B. mori* embryos (Horike and Sonobe, 1999). EPR spectroscopic studies have corroborated the presence of ferredoxin (adrenodoxin) and cytochrome P450 enzyme in the foregoing mitochondria (Shergil *et al.*, 1995) and in *Manduca* fat body mitochondria (Smith *et al.*, 1980).

The electron transfer systems appear to be structurally and functionally conserved. The cytochrome P450 reductase has been cloned in several insect species (Koener *et al.*, 1993; Hovemann *et al.*, 1997; Horike *et al.*, 2000). Similarly, the adrenodoxin reductase gene (*dare*) has been identified in *Drosophila* (Freeman *et al.*, 1999). Taken together, these data underline the similarity of cytochrome P450 enzyme function in both vertebrates and invertebrates. As there are numerous cytochrome P450 enzymes involved in various metabolic processes, the expression patterns of the electron transfer proteins are not specific to steroidogenic tissues. However, specific transcriptional or posttranscriptional regulation may occur in steroidogenic tissues, as has been shown in vertebrates. Molecular studies are needed to substantiate such hypotheses.

3.3.4.3.3. Intracellular steroid movements During ecdysteroid biosynthesis, intracellular movements of all sterol intermediates (and not just C) must necessarily occur, as the various enzymes involved in their interconversion have been localized to different subcellular compartments. In vertebrates, several proteins (in addition to the enzymatic

machinery) are expressed more or less specifically in the steroidogenic tissues, where they appear to act to promote cholesterol movements inside the cells. These proteins play complementary roles during the acute regulation of steroidogenesis. Three major steps are thought to be involved, although the mechanisms are still not fully understood. First, a sterol carrier protein (SCP-2) mediates the transfer of C, whether dissolved in the cell membrane, the ER, or within intracellular lipid droplets, to the outer mitochondrial membrane (Gallegos *et al*., 2001). Then the binding of a ligand, diazepam binding inhibitor (DBI), to a peripheral benzodiazepine receptor (PBR) is involved in the formation of a pore complex, thereby creating contact sites between the outer and inner membranes of the mitochondria (Papadopoulos, 1993). Finally (at least in the adrenal) the steroidogenic acute regulatory protein (StAR), by means of its StAR-related lipid transfer domain (START), enables a rapid increase in the transport of cholesterol from the outer to the inner mitochondrial membrane (Stocco, 2001) where the first enzyme of steroidogenesis, the cholesterol side chain cleavage cytochrome P450 (CYP11A), resides (Miller, 1988; Stocco and Clark, 1996; Black *et al*., 1994). A similar function has been attributed to the vertebrate cholesterol transporter MLN64 (metastatic lymph node 64) within the placenta (Moog-Lutz *et al*., 1997). However, while it shares the START domain with the StAR protein, MLN64 also has an additional transmembrane region.

In arthropods, the situation is somewhat different since the first step of ecdysteroid biosynthesis is microsomal instead of mitochondrial, but intracellular sterol (and ecdysterol) trafficking may nevertheless require facilitation by mechanisms similar to those observed in vertebrates (**Figure 14a**). It would first seem necessary to increase the access of C, whether localized in the cell membrane or present in cytosolic vesicles, to the 7,8-dehydrogenase in the ER. Thus, an SCP2-like protein could be involved in these sterol movements into and maybe out of the ER. Subsequently, the newly synthesized and very nonpolar 7dC must then translocate from the ER through the cytosol to the unknown organelle where it undergoes the black box oxidations, i.e., to the mitochondria, to another domain of the ER, to the peroxisome, or to some other place. If there is mitochondrial involvement at this stage of the synthesis (or later), then a StAR-like protein, i.e., Start1 (see below), may well be involved, perhaps along with DBI/PBR. Alternatively, if peroxisomal, then an SCP2-like carrier might be indicated. This movement of 7dC out of the ER and into the location of its subsequent oxidation, in analogy with the cholesterol side chain cleavage reaction of mammalian steroidogenesis, has long been hypothesized to be the rate-limiting step of ecdysteroid biosynthesis (Rees, 1985, 1995; Warren and Hétru, 1990; Warren and Gilbert, 1996) and ultimately under the control of the brain molting factor prothoracicotropic hormone (PTTH) (see **Chapter 3.2**). The final envisioned Δ^4-diketol product could then undergo hypothesized reduction by a cytosolic or membrane-bound 5β-reductase. In any case, the resulting ecdysteroid-like product, 3-dehydro-2,22,25dE (or its 3β-OH reduction product, see Section 3.3.4.2.3), must necessarily travel back to the ER to undergo 25-hydroxylation, prior to its final sequential 22- and 2-hydroxylations within the mitochondria. The now very polar, almost sugar-like steroid product 3DE (or E) is then somehow finally secreted through the cell membrane and into the hemolymph for subsequent 3β-OH reduction (if needed, see Section 3.3.5.3.2) and/or conversion to 20E in the peripheral tissues.

Homologs of the above-mentioned proteins are found across the animal kingdom, including insects. Recent studies dealing with their role in insects are consistent with their putative implication in the regulation of ecdysteroid biosynthesis (**Figure 14a**). A SCP-2-like protein has recently been identified in *Aedes aegypti* (Krebs and Lan, 2003). It has a sequence (about 40% amino acid identity with mammalian sequences) and three-dimensional structure similar to the mammalian SCP-2/SCP-X proteins (Stolowich *et al*., 2002; Dyer *et al*., 2003), suggesting a conserved role as a cholesterol transporter. In *Drosophila*, a SCP-X gene has been reported (Kitamura *et al*., 1996), but only a 1.6 kb transcript was mentioned with high expression levels in the midgut of embryos. On the other hand, an independent gene (AeSCP-2) has been identified in *Aedes* and is similar to the vertebrate SCP-2 transcript. The *Aedes* SCP-2-like protein also has a high affinity towards cholesterol, suggesting its role as a cholesterol transporter (Krebs and Lan, 2003). It presents a broad tissue distribution, but further detailed studies are needed of the expression of a SCP-2-like protein in arthropod steroidogenic tissues.

In various vertebrate steroidogenic cell models, the activation of the mitochondrial 18 kDa peripheral-type benzodiazepine receptor (PBR) by its ligand diazepam binding inhibitor (DBI) or endozepine, confers the ability to take up and release cholesterol (Papadopoulos *et al*., 1998). The diazepam-binding inhibitor (DBI) is a 10-kDa protein, which has been identified in *M. sexta* (Snyder and Feyereisen, 1993) and *D. melanogaster* (Kolmer *et al*., 1993, 1994). Homologous sequences are also

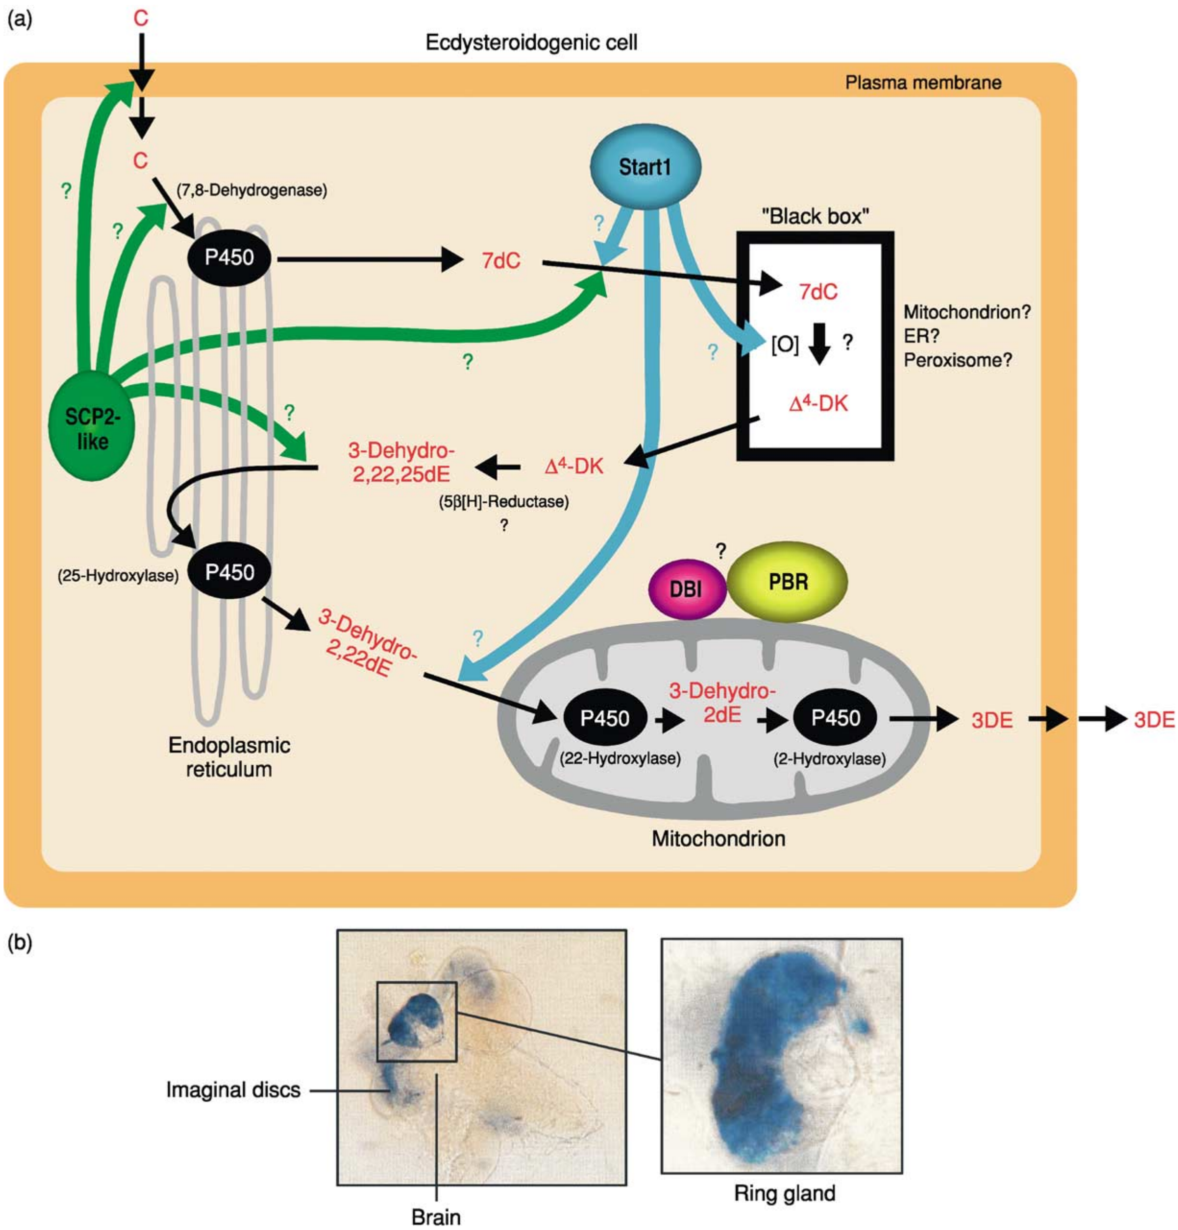

Figure 14 Proposed involvement of the hypothetical sterol carrier proteins SCP2, DBI, and StAR in insect ecdysteroidogenesis. (a) Ecdysone biosynthesis: localizations of subcellular enzymes and hypothetical intracellular movements of intermediates within the ecdysteroidogenic cell. C, cholesterol; 7dC, 7-dehydrocholesterol; D4-DK, D4-diketol; 3-dehydro-2,22,25dE, 3-dehydro-2,22,25-trideoxyecdysone (diketol); 2,22dE, 2,22-dideoxyecdysone (ketotriol); 3-dehydro-2dE, 3-dehydro-2-deoxyecdysone; 3DE, 3-dehydroecdysone; SCP2-like, sterol carrier protein 2-like; Start1, steroidogenic acute regulatory protein related lipid transfer domain protein 1; DBI, diazepam binding inhibitor; PBR, peripheral benzodiazepine receptor. (b) *In situ* hybridization of *Drosophila* L3 larvae brain ring gland complex employing an antisense *Drosophila* StAR (Start1) digoxigenin-labeled RNA probe (C. Dauphin-Villemant, A. Mesneau, and J.-P. Parvy, unpublished data).

found in other dipteran and lepidopteran species. In *M. sexta* prothoracic glands, DBI expression varies concomitantly with ecdysteroid production, and *in vitro* ecdysteroid production is stimulated by a diazepam analog (Snyder and Antwerpen, 1998). Changes in prothoracic glands of both mRNA and DBI protein levels suggest a tissue-specific regulation of this gene, consistent with a role in the regulation of ecdysteroid biosynthesis.

The capacity of steroidogenic cells during development is highly variable in arthropods, as in vertebrates, and peptide hormones induce very rapid increases in steroid production (within minutes) (see **Chapter 3.2**). The acute regulation of vertebrate

steroidogenesis seems to be the predominant role of the labile proteins StAR and its close analog MLN64 (Stocco, 2000, 2001). Similarly, stimulation of insect steroidogenesis is rapidly inhibited by cycloheximide, an inhibitor of protein synthesis, indicating the requirement of a labile protein (Keightley *et al*., 1990; Dauphin-Villemant *et al*., 1995) (see **Chapter 3.2**). Analysis of genome databases revealed related sequences in invertebrates, including *C. elegans*, *D. melanogaster*, and *A. gambiae*. One, *Start1*, is homologous not with *StAR*, but rather with *MLN64*. However, in addition to the four putative transmembrane domains (helices) of MLN64, it also contains a 122 amino acid insert of unknown function. The spatial and temporal pattern of both *Start1* message and Start1 protein expression in *Drosophila* is consistent with it being the rate-limiting factor in ecdysteroidogenesis (Roth *et al*., 2004). For instance, *in situ* hybridization using an antisense Digoxygenin-labeled probe corresponding to the sequence for *Start1* isolated from third instar total RNAs shows a strong labeling of ring glands (**Figure 14b**; C. Dauphin-Villemant, unpublished data). In a similar manner, a carotenoid binding protein (CBP) presenting similarities with the StAR family was recently identified in the *Bombyx mori* silk gland (Tabunoki *et al*., 2002). However, as it binds carotenoids rather than cholesterol, it is possible that several StAR related proteins may exist in arthropods. Clearly, further studies are needed to demonstrate the involvement of the *Drosophila* Start1 protein or any of these other proteins, in the regulation of steroidogenesis.

3.3.4.4. The Ecdysteroidogenic Tissues

3.3.4.4.1. Prothoracic glands and gonads Classically, prothoracic glands are considered as the source of ecdysteroids during postembryonic development, but they usually degenerate prior to the early adult stage. The development of new analytical techniques such as radioimmunoassay (Borst and O'Connor, 1972) allowed direct evidence to be obtained for ecdysone secretion by prothoracic glands. Using *in vitro* incubations of these organs, several authors could demonstrate that they actually secrete measurable amounts of ecdysone, and that the variations of this secretory activity are consistent with the fluctuations of hemolymph ecdysteroid levels (Chino *et al*., 1974; King *et al*., 1974; Borst and Engelmann, 1974). However, this was not a full demonstration for *de novo* synthesis. Only the *in vitro* conversion of radiolabeled cholesterol or 25-hydroxycholesterol by prothoracic glands and Y-organs provided the final argument for the *de novo* synthesis of ecdysteroids by these endocrine organs (Hoffmann *et al*., 1977; Warren *et al*., 1988a, 1988b; Böcking *et al*., 1994).

Adult insects also contain ecdysteroids, as was found in *Bombyx* (Karlson and Stamm-Menendez, 1956). The same methods used for prothoracic glands established that ovaries are a temporary ecdysteroid source, usually in adults and/or pharate adults, depending on the stage when the oocytes develop (Hagedorn *et al*., 1975; Hagedorn, 1985). Careful dissections allowed demonstration that the follicle cells surrounding terminal oocytes are able to produce these compounds *de novo* from cholesterol (Goltzené *et al*., 1978). Labeling was only observed in vitellogenic follicles (stage 10), suggesting local effects of ecdysteroids (paracrine), as expected from the inhibitory effect of ecdysteroids on selective stages of oocyte maturation (Soller *et al*., 1999). These maternal ecdysteroids can also be stored as conjugates by developing oocytes and/or are released into the hemolymph for distribution within the adult. There, they may retain specific endocrine functions such as the control of vitellogenesis, of sexual pheromone biosynthesis, or of ovarian cyclic activity.

Insect testes also contain ecdysteroids and it has been proposed that the testis interstitial tissue plays a role similar to the Leydig cells of vertebrates. When cultured *in vitro*, testes indeed release small amounts of a complex mixture of immunoreactive compounds (Loeb *et al*., 1982), and this release can be stimulated by an ecdysiotropic peptide originating in the brain (Loeb *et al*., 1988). They efficiently convert 2,22,25-trideoxyecdysone into E and 20E (Jarvis *et al*., 1994b). However, the direct evidence for a complete *de novo* biosynthetic pathway in testes is still lacking, and thus a partial synthesis starting from some downstream biosynthetic intermediate or ecdysteroid conjugate cannot be excluded at present. The amounts of ecdysteroids involved are always low as compared to those produced by ovaries, and the absence of a prominent component within the ecdysteroids released *in vitro* does not strongly argue for an endocrine function. Consistent with this hypothesis is the lack of *dib* and *phm* expression in testes, as noticed in the RT-PCR study of various *Drosophila* tissues (**Figure 12a**), although much further study is needed to affirm this result.

3.3.4.4.2. Other tissues? The idea of alternative sites of ecdysteroid production has arisen from much experimental data that do not fit with the classical scheme (Redfern, 1989; Delbecque *et al*., 1990). Prothoracic glands of *Tenebrio molitor* (Coleoptera) degenerate during the pharate pupal stage, so the pharate pupal and pupal ecdysteroid

peaks must arise from another source (Glitho *et al*., 1979). *In vitro* cultivated epidermal fragments of *Tenebrio* pupae release significant amounts of ecdysteroids, and they convert 2,22,25-trideoxyecdysone (but not C) into E. This release is connected with the epidermis cell cycle, as it can be abolished by treatment with mitomycin (Delbecque *et al*., 1990 and references therein). The prothoracic glands of larvae and pupae of the mosquito, *Ae. aegypti*, do not secrete any ecdysteroid when cultured *in vitro*, whereas fragments of thorax and abdomen do secrete ecdysteroids (Jenkins *et al*., 1992). In the same way, epidermal fragments from locust last instar nymphs secrete ecdysteroids *in vitro* (Cassier *et al*., 1980), and cell lines derived from imaginal discs display a rhythmic ecdysteroid production (Mesnier *et al*., 2000). It should be emphasized that prothoracic glands have an ectodermal origin. Therefore, the general epidermis is expected to be the source of molting hormones (see, e.g., Bückmann, 1984; Lachaise *et al*., 1993). Interestingly, it was recently demonstrated that skin is also a primary steroidogenic tissue in humans (Thiboutot *et al*., 2003).

Other approaches have raised similar questions. Insects deprived of molting glands can still molt (e.g., *Periplaneta americana*, Gersch, 1979; *M. sexta*, Sakurai *et al*., 1991); ovariectomized adult insects still contain/produce ecdysteroids (Delbecque *et al*., 1990). Thus, there are data that cannot be explained, unless an alternative ecdysteroid source is postulated. At this level, we should clearly distinguish between primary and secondary sources (Delbecque *et al*., 1990). Primary sources can be defined as tissues that are capable of the *de novo* synthesis of ecdysteroids starting from C or related phytosterols. Secondary sources release ecdysteroids following the hydroxylation of late intermediates or the hydrolysis of conjugates, and therefore do not contain the whole set of enzymes required for de novo synthesis. It is expected, with the complete characterization of all the various *Drosophila* steroidogenic enzymes, that these molecular tools will become available for other insect species as well (e.g., *Aedes*, *Tenebrio*) and they will allow the identification of the tissues that express steroidogenic enzymes in these species.

Finally, the importance and mechanism of ecdysteroid biosynthesis during early embryonic development is still not well understood. Early metabolic studies performed in *Locusta* (Koolman 1989) suggested that ecdysteroids were provided by maternal stores at this stage. However, the very existence of the lethal embryonic Halloween mutations and the results of *in situ* hybridizations using *dib*, *sad*, and *phm* probes argue for *de novo* ecdysteroid biosynthesis during early embryogenesis in *Drosophila*, as has now been described in *Bombyx* embryos (Sonobe *et al*., 1999), and not simply from the hydrolysis of maternally derived ecdysteroid stores within the developing embryo (Bownes *et al*., 1988; Grau and Gutzeit, 1990; Kozlova and Thummel, 2003).

3.3.5. Ecdysteroid Metabolism

3.3.5.1. Introduction

Early reviews are available on ecdysteroid metabolism (Rees and Isaac, 1984, 1985; Lagueux *et al*., 1984; Lafont and Koolman, 1984), including two on synthetic (Smith, 1985) and degradative (Koolman and Karlson, 1985) aspects of regulation of ecdysteroid titer in the first edition of this series, together with several articles in the book edited by Koolman (1989) and a more recent one (Rees, 1995).

In view of the diverse nature of the insect class, there is always a danger of attempting to unify their metabolic processes into common schemes. Certainly, there is considerable species variation in ecdysteroid metabolic pathways. The pathways have been primarily deduced from examination of the fate of [^{3}H]-ecdysteroids in various species of whole insects at various stages of development, or in various tissues incubated *in vitro*. Although in many cases, the metabolic products have been incompletely characterized, such studies have been complemented by the isolation and physical characterization of metabolites.

Defined changes in the ecdysteroid titer are mandatory for correct functioning of the hormone system during development. Regulation of the ecdysteroid titer involves the rates of ecdysone biosynthesis, conversion into the generally more active 20E, inactivation, and excretion. The presence of ecdysteroid carrier proteins, which may protect the hormone to a certain extent from inactivating enzymes, may influence the fate of circulating ecdysteroids. From the limited information available, there is an apparent species-dependent heterogeneity in ecdysteroid transport, with some species lacking binding proteins, whilst others differ in relation to the specificity of protein binding (Karlson, 1983; Whitehead, 1989; Koolman, 1990).

One difficulty is ensuring that some ecdysteroids that have been generally regarded as hormonally inactive metabolites do not possess biological activity in particular systems. For example, although 20E is regarded as the principal active ecdysteroid in most species, there is evidence that E, 3-dehydro-, and 26-hydroxy-ecdysteroids may have hormonal

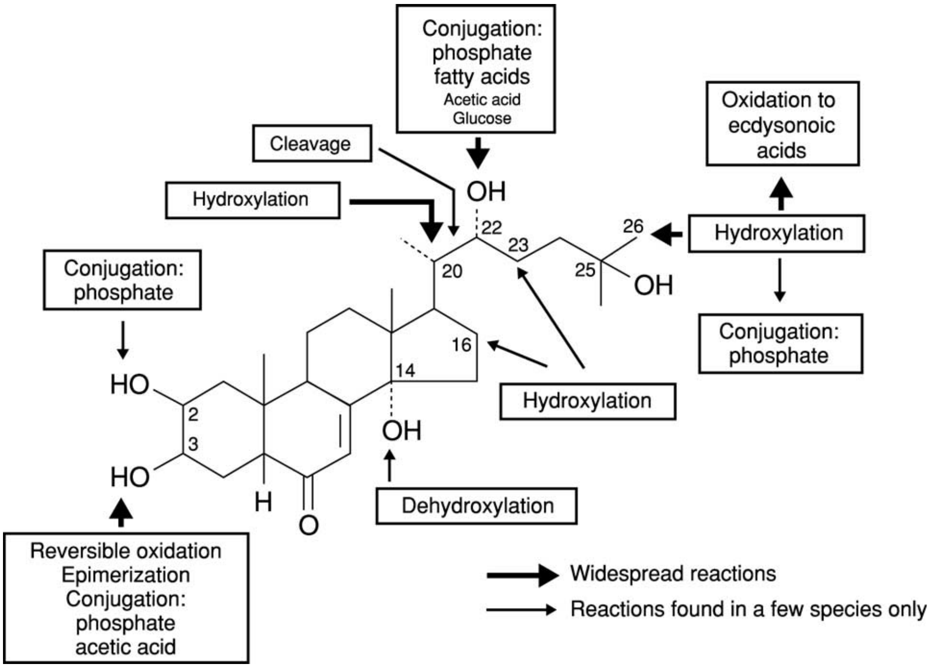

Figure 15 Major reactions of ecdysone metabolism. (Modified from Lafont, R., Connat, J.-L. **1989**. Pathways of ecdysone metabolism. In: Koolman, J. (Ed.), Ecdysone, From Chemistry to Mode of Action. Georg Thieme Verlag, Stuttgart, p. 167.)

activity in certain systems (see Lafont and Connat, 1989; Dinan, 1989). The tissues that are most active in metabolizing ecdysteroids are the fat body, Malpighian tubules and the midgut. In larvae, ecdysteroids are excreted via the gut or Malpighian tubules and occur in feces as unchanged hormones and various metabolites including conjugates, ecdysteroid acids, and 3-epiecdysteroids (Lafont and Koolman, 1984; Koolman and Karlson, 1985).

Over the years, there have been a plethora of studies on the metabolism of E in various species and the major modifications that have been detected are summarized in **Figure 15**. This concentrates on insects and does not include some more specialized transformations such as found in vertebrates. Since most of the metabolic studies have utilized $[^3H]$-ecdysone labeled in the side chain, the importance of side chain cleavage may well have been underestimated, since the labeled side chain fragment may not have been detected under the conditions used. This section will concentrate on work published since 1985. Studies *in vitro* on E metabolism in different tissues of various species (Koolman and Karlson, 1985), together with the enzymes catalyzing the reactions (Weirich, 1989), have been tabulated and reviewed.

3.3.5.2. Ecdysone 20-Monooxygenase

E, either produced directly by the prothoracic glands or in many Lepidoptera via reduction of 3dE by hemolymph 3-dehydroecdysone 3β-reductase, undergoes ecdysone 20-monooxygenase-catalyzed hydroxylation to yield 20E (**Figure 11**). The 20-hydroxylation reaction is important in the production of 20E, which is generally far more active than E. Earlier work on ecdysone 20-monooxygenase (ecdysone 20-hydroxylase; EC 1.14.99.22) is covered in several reviews (Weirich *et al.*, 1984; Lafont and Koolman, 1984; Smith, 1985; Weirich, 1989; Grieneisen, 1994; Rees, 1995).

3.3.5.2.1. Properties

3.3.5.2.1.1. Species and tissues Early studies on ecdysone 20-monooxygenase in certain tissues of various insect species, together with the biochemical properties of some of these enzymes have been reviewed (Weirich *et al.*, 1984; Smith, 1985). Recently, the gene coding for ecdysone 20-monooxygenase activity in *Drosophila* (*shd*, CYP314A1) has been identified and characterized (Petryk *et al.*, 2003; see Section 3.3.4.3.1). The enzyme is expressed in several peripheral tissues, primarily in the fat body, Malpighian tubules, and midgut. Although generally lower activity may occur in certain other tissues including the ovaries and integument, it is absent from prothoracic glands.

3.3.5.2.1.2. Subcellular distribution Depending on species and tissue, ecdysone 20-monooxygenase may be either mitochondrial or microsomal or occur

in both subcellular fractions. For example, a thorough study has established the occurrence of both high mitochondrial and microsomal activities in midgut from *M. sexta* (Weirich *et al.*, 1985). Although the mitochondrial enzyme has the higher V_{max}, since it also has the higher apparent K_M (E) (1.63×10^{-5} M versus 3.67×10^{-7} M for the microsomal one), at physiological E concentrations (10^{-7}–10^{-8} M), it is only one-eighth to one-tenth as active as the microsomal enzyme. Thus, the microsomal ecdysone 20-monooxygenase is the primary enzyme activity in *Manduca* midgut (Weirich *et al.*, 1996). Similarly, in larvae of *Drosophila* and fed adult females of *Aedes aegypti*, dual localization of enzymatic activity has been shown (Smith and Mitchell, 1986; Mitchell and Smith, 1986; see Section 3.3.4.3.1). Furthermore, in larvae of the housefly, *Musca domestica*, although appreciable ecdysone 20-monooxygenase activity occurs in both mitochondrial and microsomal fractions, pretreatment of larvae with E results in an increase in V_{max} and a decrease in K_M values in mitochondria, but not in microsomes. This suggested that the mitochondrial E 20-monooxygenase is under regulatory control by E in the larval stage and that only such activity has a physiological role during development in *M. domestica* (Agosin *et al.*, 1988). Since one of the mitochondrial cytochrome P450 species fractionated from E-induced mitochondria catalyzed the reaction at significantly higher rates than the other five species in a reconstituted system, it was postulated that the 20-monooxygenase is a mitochondrial process that requires the induction of a low K_M P450 species by ecdysone (Agosin and Srivatsan, 1991). In adults of both sexes of the cricket, *Gryllus bimaculatus*, E 20-monooxygenase activity is located primarily in the microsomal fraction of the midgut, with peak activity at day 4 following ecdysis; no detectable activity was observed in fat body, ovaries, Malpighian tubules, and carcass tissues (Liebrich *et al.*, 1991; Liebrich and Hoffmann, 1991).

3.3.5.2.1.3. Cofactor requirements and cytochrome P450 properties Ecdysone 20-monooxygenase requires NADPH as a source of reducing equivalents. As in the case of vertebrates, the mitochondrial system can use other secondary sources of reducing equivalents such as NADH or Krebs cycle intermediates, presumably by intramitochondrial generation of NADPH via transhydrogenation of $NADP^+$ (Greenwood and Rees, 1984; Smith, 1985). Similarly, a requirement of the 20-monooxygenase for oxygen has been firmly established. Evidence for involvement of cytochrome P450 has been obtained by inhibition of activity with carbon monoxide, its maximal reversal with light at 450 nm as revealed by a photochemical action spectrum, use of a range of specific inhibitors of cytochrome P-450, together with demonstration of the presence of the protein by CO difference spectroscopy (see Smith, 1985).

3.3.5.2.1.4. Substrate specificity Although reconstituted pure vertebrate steroid hydroxylating cytochrome P450s exhibit substrate specificity, it is not absolute and may hydroxylate more than one position on the steroid substrate albeit at different rates (Sato *et al.*, 1978). Since pure cytochrome $P450_{ecdysone}$ has not been available for such reconstitution experiments (see Section 3.3.4.3.1), only preliminary data are available using mitochondrial or microsomal preparations where multiple P450s may occur. *Locusta migratoria* microsomes do not react with 2β-acetoxy- or 3-dehydroecdysone, nor with the 5α-epimer of E; neither will they hydroxylate 20E nor 3d20E at any other position (Feyereisen and Durst, 1978). In the case of *Manduca* fat body mitochondria, the results of a competition assay, which is presumed to reflect enzyme–substrate binding, surprisingly showed that the most effective competitor was not E, but 2,25-dideoxyecdysone, followed in order of decreasing competition by E, 22-deoxyecdysone, 2-deoxyecdysone, 22,25-dideoxyecdysone, and 2,22,25-trideoxy-ecdysone (Smith *et al.*, 1980). Interestingly, 20-hydroxylation of 26-hydroxyecdysone, ecdysonoic acid, and 3-epiecdysone has been observed in *P. brassicae* (Lafont *et al.*, 1980).

3.3.5.2.1.5. Kinetics and product inhibition The K_M and V_{max} values determined for the various mitochondrial and microsomal E 20-monooxygenase systems show substantial differences (Weirich *et al.*, 1984; Smith, 1985). However, the extent to which these differences are real or reflect different detailed methodologies is uncertain (see Smith, 1985). However, several studies have demonstrated competitive inhibition of the enzyme system by its product, 20E.

3.3.5.2.2. Control during development Early studies on regulation of E 20-monooxygenase activity have been comprehensively reviewed (Smith, 1985).

3.3.5.2.2.1. Developmental changes in ecdysone 20-monooxygenase activity Although many early studies on changes in the metabolism of E *in vivo* suggested that E 20-monooxygenase activities vary during development, definitive demonstration of this required *in vitro* studies, since several factors

could conceivably complicate the former (see Smith, 1985).

In the migratory locust, *Locusta migratoria*, peaks in E 20-monooxygenase activity, microsomal cytochrome P450 levels, and NADPH cytochrome *c* reductase activity in both fat body and Malpighian tubules coincided with the peak of 20E in the hemolymph (Feyereisen and Durst, 1980). This suggested that the increases in E 20-monooxygenase activities were due to increased amounts of the monooxygenase components. However, in several species, the peak of E 20-monooxygenase activity preceded that of the hormone titer during the last larval instar (*Schistocerca gregaria* Malpighian tubules: Johnson and Rees, 1977; Gande *et al*., 1979; *Calliphora vicina*: Young, 1976). Similarly, in the fifth larval instar of *Manduca*, fat body and midgut monooxygenase activities exhibited 10-fold and 60-fold fluctuations, respectively, that were not temporally coincident with one another, or with the major hemolymph ecdysteroid titer peak (Smith *et al*., 1983). These peak activities for fat body and midgut monooxygenases were temporally coincident and succedent, respectively, with the small hemolymph peak of ecdysteroid titer on day 4 that is responsible for the change in commitment during larval–pupal reprogramming; both activities were at basal levels during the major hemolymph ecdysteroid titer peak on day 7–8.

The exact significance of these E 20-monooxygenase developmental profiles remains obscure. Since the apparent K_M values for the fat body and midgut systems were fairly constant during the instar, whereas the apparent V_{max} values in each tissue fluctuated in a manner that was temporally and quantitatively coincident with the fluctuations in monooxygenase activity, it suggested that the changes in these activities were due to changes in amounts of the enzymes. More recently, the peak in *Manduca* midgut E 20-monooxygenase activity at the onset of wandering on day 5 has been further examined (Weirich, 1997). During the day preceding the peak, the microsomal activity increased 60-fold (total activity) or 115-fold (specific activity) and decreased gradually within 2 days after the peak. In contrast, the mitochondrial activity increased only 1.3- to 2.4-fold (total and specific activities, respectively) before the peak, but declined more rapidly than the microsomal activity after the peak. This indicates that mitochondrial and microsomal E 20-monooxygenase activities are controlled independently and that changes in the physiological rate of E 20-hydroxylation in the midgut are affected primarily by changes in the microsomal E 20-monooxygenase activities. Further studies on *M. sexta* showed that basal levels of E 20-monooxygenase activity occurred during the later stages of embryogenesis and that a peak of monooxygenase activity occurred late in the fourth instar in both fat body and midgut at the time of spiracle apolysis (Mitchell *et al*., 1999). Both the fat body and midgut hydroxylase activities were basal during the pupal stage and only rose late in pharate–adult development, just prior to adult eclosion.

In another lepidopteran, the gypsy moth *Lymantria dispar*, preliminary studies with homogenates of various tissues taken at different times in the fifth instar surprisingly showed that E 20-monooxygenase activity in fat body, midgut, and Malpighian tubules exhibited peak activity coinciding with the peak in the hemolymph ecdysteroid titer on the penultimate day of the instar (Weirich and Bell, 1997). In *P. brassicae*, E 20-hydroxylase activity occurs in microsomes of pupal wing discs, with an apparent K_M of 58 nM for E. The activity varied during pupal–adult development with a maximum on day 4, a time when ecdysteroid titers are high (Blais and Lafont, 1986). Although the activity is low, the peak activity is sufficient to hydroxylate 25% of endogenous E in pupae. In eggs of the silkworm, *B. mori*, during embryonic development, E 20-monooxygenase activity was primarily microsomal and remained low in diapause eggs, whereas that in nondiapause eggs increased from the gastrula stage (Horike and Sonobe, 1999). This increase in 20-monooxygenase activity was prevented by actinomycin D and α-amanitin, suggesting the requirement for gene transcription. In the last larval stage of *Diploptera punctata*, maximal 20-monooxygenase activity of midgut homogenates, which was primarily microsomal, occurred on days 5–9, whereas the hemolymph ecdysteroid titer exhibited a small peak on day 10 with a major one on day 17 (Halliday *et al*., 1986).

In *Drosophila*, E 20-monooxygenase activity has been assayed in homogenates throughout the life cycle (Mitchell and Smith, 1988; Petryk *et al*., 2003; see Section 3.3.4.3.1). There was a small peak of enzymatic activity in the egg that was temporally coincident with the major peak in the egg ecdysteroid titer. This was followed by several larger fluctuations in activity during the first, second, and early third larval stadia, with a large peak during the wandering stage that remained high during early pupariation, before dropping to basal levels by pupation and remaining at these low levels through to adults. The major peak in E 20-monooxygenase activity during the wandering stage and early pupariation is temporally coincident with the major ecdysteroid titer peak that occurs at puparium

formation. Similarly, in the Diptera *Neobellieria bullata* and *Parasarcophaga argyrostoma* fat body microsomal E 20-monooxygenase activity exhibits a peak at the beginning of wandering behavior in the third instar (Darvas *et al*., 1993). Clearly, the exact significance of the developmental profiles in E 20-monooxygenase activities during development and, particularly, in relation to the ecdysteroid titer in various species is far from clear.

3.3.5.2.2.2. Factors affecting ecdysone 20-monooxygenase activity Not only is little known about the physiological significance of the developmental fluctuations in ecdysone 20-monooxygenase during development, but the factors and mechanisms responsible for such changes are ill understood. As alluded to earlier, the product of the reaction, 20E, is a competitive inhibitor, although on the basis of K_i values and hormone titers, there is doubt as to whether 20E could affect the monooxygenase activity under physiological conditions in all species examined (see Smith, 1985).

In certain species, there is evidence that E or 20E may induce E 20-monooxygenase systems. For example, in last instar larvae of *L. migratoria*, where the peak in ecdysteroid titer and E 20-monooxygenase activity are coincident, injection of E or 20E at an earlier time led to selective induction of cytochrome P450 systems, including E 20-monooxygenase, lauric acid ω-hydroxylase, NADPH-cytochrome *c* reductase, and cytochrome P450 (Feyereisen and Durst, 1980). This induction is apparently a specific effect of active molting hormones since 22-isoecdysone and 22,25-dideoxyecdysone were inactive. Such induction apparently requires protein synthesis, since it is abolished after simultaneous injection of E and actinomycin D, puromycin, and cycloheximide. Furthermore, involvement of the brain in this induction by E is ruled out, since it was observed in isolated abdomens.

Studies on housefly larvae corroborate regulation of E 20-monooxygenase activity by E (Srivatsan *et al*., 1987). Interestingly, although both mitochondria and microsomes catalyze the reaction, only the former E 20-monooxygenase appears to be regulated by E.

In the midgut of final larval instar tobacco hornworm, *Manduca*, the 50-fold increase in E 20-monooxygenase activity at the onset of the wandering stage, is prevented by actinomycin D and cycloheximide, indicating a requirement for transcription and protein synthesis (Keogh *et al*., 1989). This increase in 20-monooxygenase activity could also be elicited in head (but not thoracic) ligated animals by a brain-retrocerebral complex factor(s) released at the time of prothoracicotropic hormone (PTTH) release (see **Chapter 3.2**). It was reported that E or 20E could elicit the increase in monooxygenase activity in both head and thoracic ligated animals, suggesting the operation of a neuroendocrine–endocrine axis (PTTH → prothoracic glands → E → midgut) in the induction. Furthermore, it was reported that the ecdysteroid receptor agonist, RH 5849, could also elicit the increase in midgut E 20-monooxygenase activity in head or thoracic ligated larvae (Keogh and Smith, 1991). However, the finding that neither 20E nor RH5849 induced E 20-monooxygenase activity, but rather ecdysteroid 26-hydroxylase activity, in the cotton leafworm, *Spodoptera littoralis* (Chen *et al*., 1994b; see Section 3.3.5.3.2) prompted the re-investigation of the situation in *Manduca* midgut. In this study, it was shown that although 20E and RH5849 could induce E 20-monooxygenase in subcellular fractions of midgut of *Manduca*, there was a much stronger induction of ecdysteroid 26-hydroxylase activity (Williams *et al*., 1997). In the original studies (Keogh *et al*., 1989; Keogh and Smith, 1991), 26-hydroxylation was not detected, presumably because the thin-layer chromatography system used for the assay may not have resolved 20E and 26-hydroxyecdysone.

In fat body of sixth larval instar *S. littoralis*, E 20-monooxygenase activity is predominantly mitochondrial, with much less activity in the microsomes (Hoggard and Rees, 1988). The former activity exhibits a peak of activity during the instar at 72 h, when the larvae stop feeding (Chen *et al*., 1994a). To ask the question as to what is the molecular mechanism underlying this increased activity, various antibodies raised against components of vertebrate mitochondrial steroidogenic enzyme systems have been used as potential probes for the corresponding insect proteins. Since correlation was observed between developmental changes in mitochondrial E 20-monooxygenase activity and the abundance of polypeptides recognized by cytochrome $P450_{11\beta}$ antibody and a polypeptide recognized by the adrenodoxin reductase antibody, it suggests that developmental changes in the abundance of components of the monooxygenase system may be important in developmental regulation of the enzyme expression (Chen *et al*., 1994a).

There is evidence that E 20-monooxygenase activity may also be influenced by dietary factors, including plant flavonoids and other allelochemicals. For example, assay of activities *in vitro* of E 20-monooxygenase from certain species has demonstrated that a range of plant flavonoids and other allelochemicals, including azadirachtin, significantly inhibit the activity in a dose-dependent manner,

whereas certain flavonols and other allelochemicals stimulate activity (Smith and Mitchell, 1988; Mitchell *et al*., 1993). However, none of the compounds tested elicited effects at very low concentrations. Furthermore, studies on the influence of dietary allelochemicals on midgut microsomal E 20-monooxygenase activity in the fall armyworm, *Spodoptera frugiperda*, have shown that various indoles, flavonoids, monoterpenes, sesquiterpenes, coumarins, methylenedioxyphenyl compounds, and ketohydrocarbons all caused significant stimulation of activity (Yu, 1995, 2000). Significantly, enzyme inducibility was different between E 20-monooxygenase and xenobiotic-metabolizing cytochrome P450 monooxygenases.

In addition, there have been numerous studies on the effects of a plethora of synthetic inhibitors on E 20-monooxygenase activity in various species (e.g., Kulcsar *et al*., 1991; Darvas *et al*., 1992; Jarvis *et al*., 1994a).

3.3.5.2.3. Potential modulation by covalent modification The initial indication that hormonal factors might regulate ecdysteroid metabolism was furnished by the demonstration that a forskolin-induced increase in intracellular cyclic AMP in *Calliphora* fat body *in vitro* led to decreased rates of conversion of E into 20E and of the latter to other metabolites (Lehmann and Koolman, 1986, 1989). Thus, it was suggested that since forskolin mimics the action of peptide hormones by activating the adenylate cyclase system (see **Chapter 3.2**), a peptide hormone, possibly a neuropeptide, might be involved in the regulation of E metabolism. Such activation of adenylate cyclase leads to an increase in intracellular cAMP, which enhances protein (enzyme) phosphorylation via cAMP-dependent protein kinases (see **Chapter 3.2**). Such a process as part of a reversible phosphorylation-dephosphorylation of enzymes provides a mechanism for rapid modulation of enzymatic activities. In the case of vertebrate mitochondria, such a control mechanism has been reported only for a few enzyme complexes. In such systems, relevant endogenous mitochondrial protein kinase and phosphoprotein phosphatase activities have been demonstrated (see Hoggard and Rees, 1988). In fact, experimental support for such modulation of E 20-monooxygenase activity by phosphorylation-dephosphorylation has been obtained. In the case of both the microsomal and broken mitochondrial fractions from fat body of *S. littoralis*, experiments involving treatments with phosphatase inhibitors, exogenous phosphatase, protein kinase, or the adenylate cyclase activator, forskolin, provide indirect evidence that the enzyme system may exist in an active phosphorylated state and inactive dephosphorylated state (Hoggard and Rees, 1988; Hoggard *et al*., 1989). However, confirmation of this notion requires more definitive direct evidence, including direct demonstration of the incorporation of labeled phosphate into components of the E 20-monooxygenase, together with demonstration of the occurrence of an appropriate mitochondrial protein kinase and protein phosphatase.

There are many reports of the phosphorylation of cytochrome P450s (Koch and Waxman, 1991), including steroidogenic $P450_{11\beta}$ from bovine adrenal mitochondria (Defaye *et al*., 1982), with limited evidence for the physiological significance of the phenomenon. The activity of the microsomal cytochrome P450-dependent cholesterol 7α-hydroxylase may also be modulated by phosphorylation-dephosphorylation (Goodwin *et al*., 1982).

Since the pharmacologically inactive forskolin derivative, 1,9-dideoxy-forskolin, as well as forskolin, induced a dose-dependent inhibition of E 20-monooxygenase, the effect must be direct rather than via activation of adenylate cyclase (Keogh *et al*., 1992). Thus, care must be exercised in the design of such experiments to avoid possible misinterpretation of data.

3.3.5.3. Ecdysteroid Inactivation and Storage

Insect development is absolutely dependent on defined changes in ecdysteroid titer. We have already considered the major hormone activation step, the E 20-monooxygenase-catalyzed reaction, and will now consider the major pathways contributing to hormone inactivation. As alluded to in Section 3.3.1, there are many reviews covering ecdysteroid metabolism and inactivation. It is difficult to establish unequivocally that a particular compound is an inactivation product, since an ecdysteroid that is essentially hormonally inactive in one assay may have activity in other systems (Dinan, 1989; Lafont and Connat, 1989).

Early studies on $[^3H]$-ecdysteroid metabolism in insects and other arthropods frequently reported the formation of polar products that were hydrolyzable with various hydrolytic enzymes, especially the so-called "*Helix pomatia* sulfatase," releasing free ecdysteroids. However, unless the enzyme is absolutely pure, no conclusion can be drawn regarding the nature of the conjugate.

It is convenient to consider metabolism and inactivation of ecdysteroids in relation to (1) potential re-utilization of the products from adult females during embryogenesis, or (2) removal of hormonal activity and excretion.

3.3.5.3.1. Ecdysteroid storage, utilization, and inactivation

3.3.5.3.1.1. Phosphate conjugates Ecdysteroid "storage" has been reviewed (Isaac and Slinger, 1989). Initially, a relatively high concentration of polar conjugated ecdysteroids was reported in *Bombyx* eggs (Mizuno and Ohnishi, 1975). However, the demonstration that ecdysteroids in locust ovaries/eggs occurred almost exclusively as polar conjugates (Dinan and Rees, 1981a) and their identification as the 22-phosphate derivatives in *S. gregaria* (Rees and Isaac, 1984) and *L. migratoria* (Lagueux *et al.*, 1984) opened the way for more definitive investigations in various species. Significantly, these maternal conjugates are phosphorylated at C_{22} and are presumably inactive, since a free 22*R* hydroxyl group is important for high hormonal activity. The ovarian ecdysiosynthetic tissue has been shown to be the follicle cells (see Lagueux *et al.*, 1984) and the cytosolic phosphotransferase from *S. gregaria* follicle cells has been characterized (Kabbouh and Rees, 1991a). The enzyme is dependent on ATP/Mg^{2+} for high activity, and activity varies during ovarian development, reaching a peak at the end of oogenesis in agreement with the titer of ecdysteroid 22-phosphates in the oocytes. Furthermore, enzymatic activity can be induced in terminal oocytes by E or 20E treatment, which suggests a physiological mechanism of increasing conjugation as biosynthesis of ecdysteroids in follicle cells proceeds (Kabbouh and Rees, unpublished data).

The majority of the ovarian ecdysteroid conjugates, together with some free hormone, was passed into the oocytes (Dinan and Rees, 1981a; see Rees and Isaac, 1984; Hoffmann and Lagueux, 1985). During embryogenesis, locusts undergo several molts and cycles of cuticulogenesis coincident with peak titers of free ecdysteroids (Sall *et al.*, 1983). Support for the hypothesis that the ecdysteroid 22-phosphates, following enzymatic hydrolysis, could at least provide one source of hormone in embryogenesis, particularly before differentiation of the prothoracic glands, was provided by demonstration of enzymatic hydrolysis of conjugates in a cell-free system from embryos (Isaac *et al.*, 1983). Significantly, activity of the enzyme increases around the time of greater utilization of the conjugates, which also corresponds to an increase in free ecdysteroid titer (Scalia *et al.*, 1987). Moreover, an ecdysteroid-phosphate phosphatase was recently purified and cloned from *Bombyx* embryos and shown to be active only in nondiapausing eggs (Yamada and Sonobe, 2003). In several species, there is no doubt that embryonic synthesis of ecdysteroids occurs in the later stages. Reviews on the role of ecdysteroids in reproduction and embryonic development are available (Hagedorn, 1985; Hoffmann and Lagueux, 1985).

The egg is a closed system and, therefore, decreases in the embryonic hormone titer occur largely by metabolic inactivation, with accumulation of products prior to emergence (Dinan and Rees, 1981b). This accumulation facilitated the identification of a number of new ecdysteroid derivatives, presumed to be inactivation products, including ecdysteroid 2-phosphate 3-acetate derivatives, 3-epi-2-deoxyecdysone 3-phosphate, and ecdysteroid 26-oic acids (see Rees and Isaac, 1984; Hoffmann and Lagueux, 1985; Rees and Isaac, 1985). **Figure 16** shows probable metabolic pathways of the major ecdysteroid 22-phosphates in developing eggs of *S. gregaria* (Rees and Isaac, 1984).

In *S. gregaria*, at the beginning of embryonic development, the ecdysteroids (conjugates and free) occur only in the yolk, whereas after blastokinesis, they occur in the embryo (Scalia *et al.*, 1987). *Locusta migratoria* produce diapause eggs under short-day (SD) conditions and nondiapause eggs under long-day (LD) conditions. The demonstration that the total detected ecdysteroids (primarily phosphate conjugates) in newly laid eggs was more than three times higher in nondiapause eggs than in diapause eggs suggests that ecdysteroids may be involved in the control of embryonic diapause in this species (Tawfik *et al.*, 2002).

Surprisingly, in *Manduca*, the major conjugate in newly laid eggs is 26-hydroxyecdysone 26-phosphate (Thompson *et al.*, 1985b). This compound undergoes hydrolysis during embryogenesis, with 20-hydroxylation of the released hormone occurring, yielding 20,26-dihydroxyecdysone, followed by reconjugation of 26-hydroxyecdysone to produce the 22-glucoside derivative; formation of 3α-epimers and 26-oic acids also occurs during embryogenesis (Warren *et al.*, 1986; Thompson *et al.*, 1987b, 1988). The proposed pathways of metabolism of 26-hydroxyecdysone 26-phosphate in the developing embryos of *Manduca* are given in **Figure 17**.

Early in embryogenesis, much of the 26-hydroxyecdysone 26-phosphate is hydrolysed, resulting in a peak of 26-hydroxyecdysone just prior to the appearance of the first serosal cuticle (Dorn *et al.*, 1987). The 20,26-dihydroxyecdysone titer reaches a peak at about the time of deposition of the first larval cuticle late in embryogenesis, raising the possibility that this ecdysteroid may have a hormonal role at this stage of development (Warren *et al.*, 1986). Significantly, the concentrations of E and 20E are minimal throughout embryogenesis. That the foregoing metabolic changes are related to

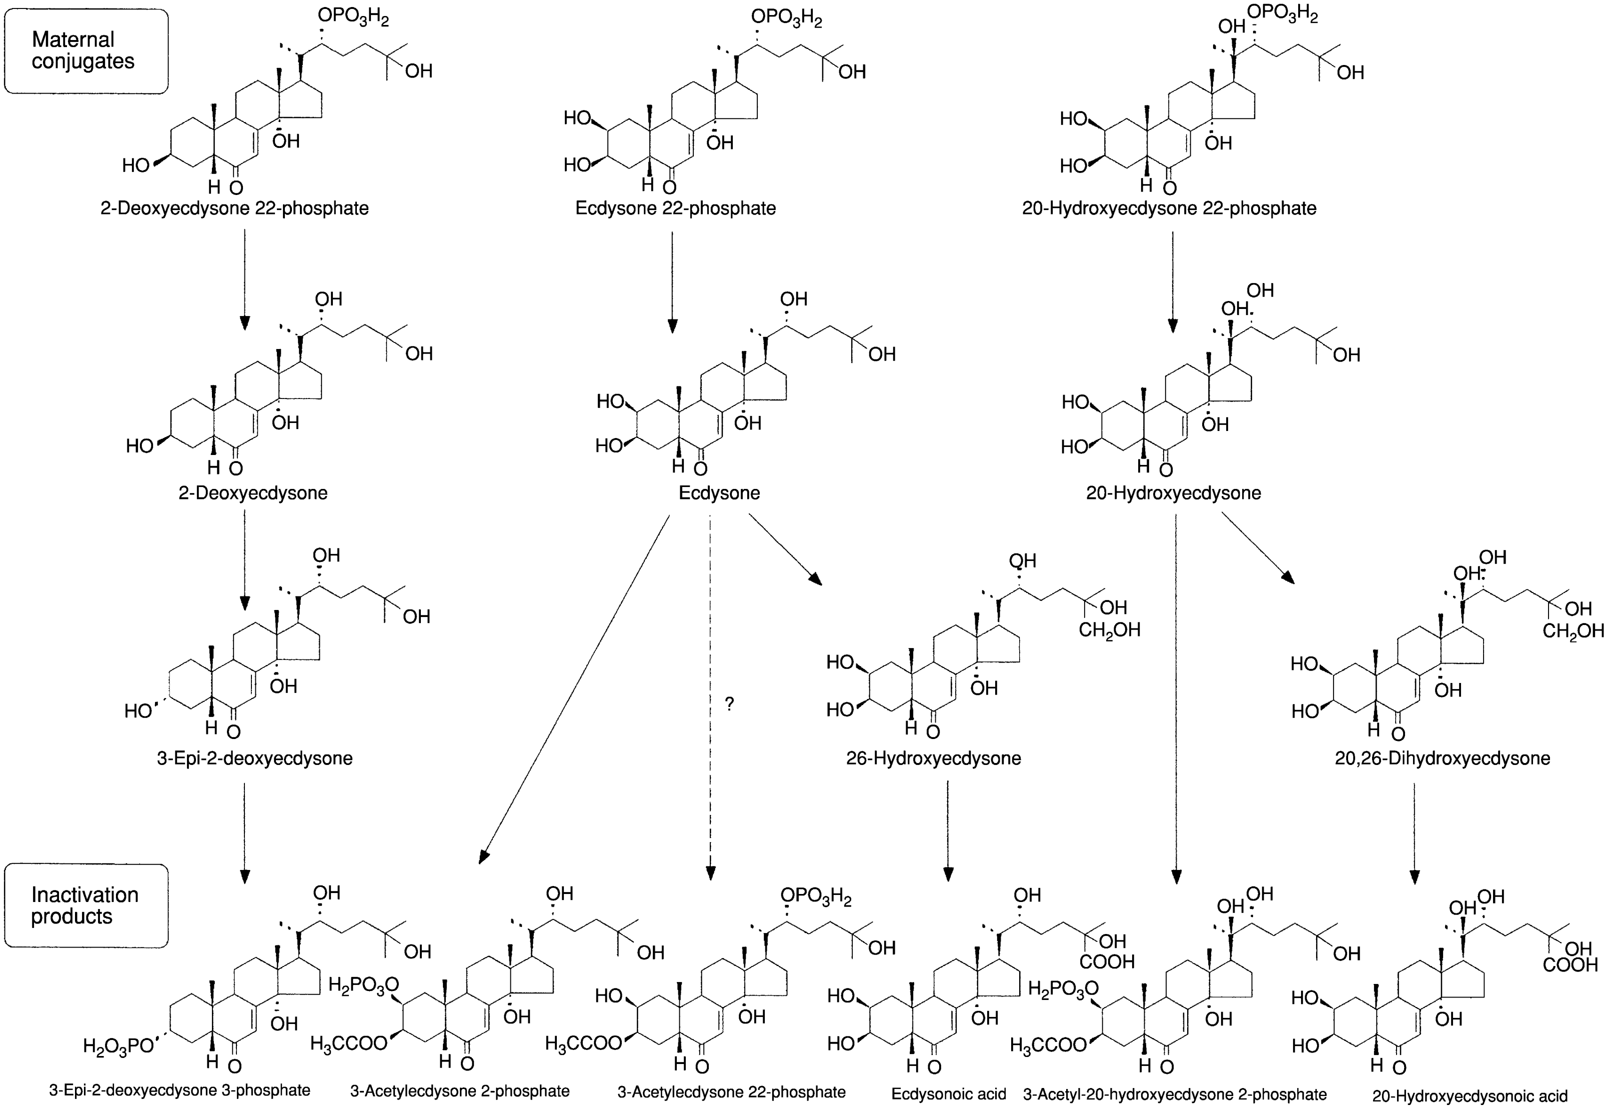

Figure 16 Probable metabolic pathways of the major ecdysteroid 22-phosphates in developing eggs of *Schistocerca gregaria*. (Modified from Rees, H.H., Isaac, R.E. **1984**. Biosynthesis of ovarian ecdysteroid phosphates and their metabolic fate during embryogenesis in *Schistocerca gregaria*. In: Hoffmann, J.A., Porchet, M. (Eds.), Biosynthesis, Metabolism and Mode of Action of Invertebrate Hormones. Springer-Verlag, Berlin, pp. 181–195.)

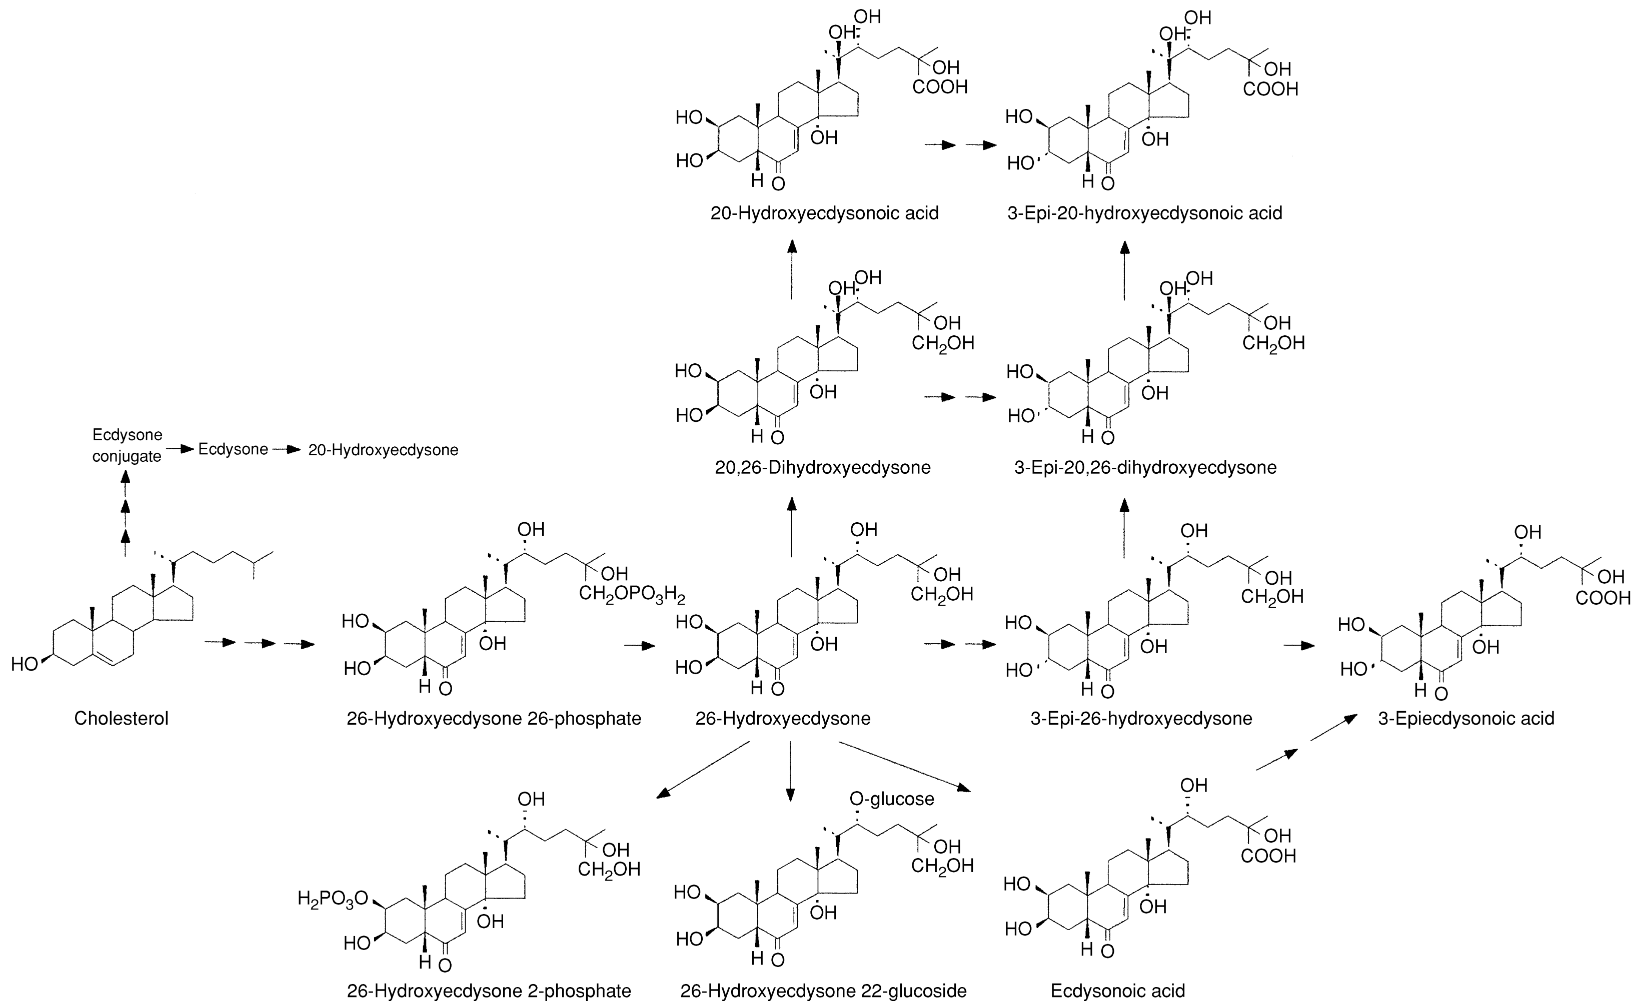

Figure 17 Proposed pathways of metabolism of 26-hydroxyecdysone 26-phosphate during embryogenesis of *M. sexta* (modified from Thompson, M.J., Svoboda, J.A., Lozano, R., Wilzer, K.R., **1988**. Profile of free and conjugated ecdysteroids and ecdysteroid acids during embryonic development of *Manduca sexta* (L.) following maternal incorporation of [^{14}C] cholesterol. *Arch. Insect Biochem. Physiol. 7*, 157–172. by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

embryogenesis is indicated by their virtual absence in incubated unfertilized eggs of *Manduca* (Feldlaufer *et al*., 1988). A plethora of free ecdysteroids and phosphate conjugates have been isolated from ovaries of the silkworm, *B. mori*, and include the following: E, 20E, 2-deoxyecdysone, 2-deoxy-20-hydroxyecdysone, 2,22-dideoxy-20-hydroxyecdysone and their 22-phosphates, bombycosterol and bombycosterol 3-phosphate (Ohnishi, 1986; Ohnishi *et al*., 1989), 22-deoxy-20-hydroxyecdysone and its 3-phosphate (Kamba *et al*., 1994), 3-epi-22-deoxy-20-hydroxyecdysone and its 2-phosphate (Mamiya *et al*., 1995), 3-epi-22-deoxy-20,26-dihydroxyecdysone, plus 3-epi-22-deoxy-16β, 20-dihydroxyecdysone and their 2-phosphates (Kamba *et al*., 2000b), as well as 2,22-dideoxy-23-hydroxyecdysone and its 3-phosphate (Kamba *et al*., 2000a). Although the metabolic relationships of many of the foregoing ecdysteroids can be surmised, they await experimental verification. The occurrence of 23- and 16β-hydroxy ecdysteroids is unusual. An ATP: ecdysteroid phosphotransferase that is active on a number of ecdysteroid substrates has been demonstrated in *B. mori* ovaries (Takahashi *et al*., 1992).

Evidence has been furnished suggesting that 20E, acting via the receptor (see **Chapter 3.5**), is responsible for the developmental difference between diapause and nondiapause in *B. mori* embryos and that a continuous supply of 20E may be required to induce embryonic development (Makka *et al*., 2002). In agreement with this is evidence suggesting that 20-hydroxylation of E may be a rate-limiting step in diapause silkworm eggs (Sonobe *et al*., 1999). Furthermore, dephosphorylation of ecdysone 22-phosphate and its subsequent hydroxylation at C_{20} and C_{26} are prominent in nondiapause eggs, whereas phosphorylation of E is a major process in diapause eggs (Makka and Sonobe, 2000). Surprisingly, in *S. littoralis*, the newly laid eggs contain primarily 2-deoxyecdysone 22-phosphate (Rees, 1995).

3.3.5.3.1.2. Fatty acyl conjugates Quite different types of conjugates, viz. apolar ecdysteroid 22-fatty acyl esters, originally found in tick ovaries and eggs (Wigglesworth *et al*., 1985; Crosby *et al*., 1986a) (see **Chapter 3.16**), also occur in such tissues in certain Orthoptera. In the tick, *Boophilus microplus*, such conjugates appear to function as inactive, storage forms of maternal hormone, being utilized in early embryogenesis and undergoing subsequent inactivation by 20E-oic acid formation in conjunction with re-conjugation (Crosby *et al*., 1986b). However, the situation is complicated, since eggs of all tick species do not contain significant ecdysteroid 22-fatty acyl esters, some containing appreciable free hormones.

Analogous apolar ecdysone 22-fatty acyl esters, produced by the ovaries, have been identified in newly laid eggs of the house cricket, *Acheta domesticus* (Whiting and Dinan, 1989). The rate of fatty acylation by ovaries is developmentally regulated, increasing as the ovaries increase in size (Whiting *et al*., 1997). Evidence suggests that the ecdysone 22-fatty acyl esters undergo hydrolysis during embryogenesis, with the resulting E being converted to 20E, which is then inactivated by double conjugation, first with an uncharacterized polar moiety, followed by 22-fatty acylation (Whiting *et al*., 1993; Dinan, 1997).

The apolar esters in eggs of another orthopteran, the cockroach, *Periplaneta americana*, differ slightly in chromatographic properties from ecdysteroid 22-fatty acyl esters, although free ecdysteroids are released by hydrolysis with *Helix pomatia* enzymes or esterases (Slinger *et al*., 1986; Slinger and Isaac, 1988a). A storage role is suggested for these apolar conjugates, since they undergo hydrolysis during the first third of embryogenesis when there is also an increase in free and polar conjugated ecdysteroids (Slinger and Isaac, 1988b). Synthesis of such apolar esters by an ovary microsomal fraction from *P. americana* requires fatty acyl-CoA as cosubstrate, indicating that the enzyme is an acyl-CoA: ecdysone acyltransferase and not a hydrolase (Slinger and Isaac, 1988c).

Interestingly, significant levels of apolar or polar ecdysteroid conjugates do not occur in newly laid eggs of another cricket species, *Gryllus bimaculatus* (Espig *et al*., 1989). Similarly, it is noteworthy that significant amounts of detectable maternal ecdysteroid conjugates have not been reported in newlylaid eggs of many insect species (see e.g., Hoffmann and Lagueux 1985; Isaac and Slinger, 1989).

Comparison of the sequence similarity of *Drosophila* vitellins and part of the porcine triacylglycerol lipase, led to the intriguing hypothesis that ecdysteroid fatty acyl ester may bind to vitellin in the eggs as storage forms, the conjugates being made available for enzymic hydrolysis as the vitellin is degraded during embryogenesis (Bownes *et al*., 1988; Bownes, 1992). Such candidate ecdysteroid 22-fatty acyl esters are produced in adult female *Drosophila*, together with ecdysone 22-phosphate (Grau and Lafont, 1994b; Grau *et al*., 1995). However, the significance of binding of ecdysone 22-phosphate to an approx. 50 kDa protein in D*rosophila* ovaries is unclear at present (Grau *et al*., 1995).

3.3.5.3.2. Inactivation and excretion in immature stages Ecdysteroids such as E and 20E may be excreted *per se* or as metabolites via the gut or Malpighian tubules. Ecdysteroid metabolizing enzymes, particularly in the fat body, midgut, and Malpighian tubules, may facilitate excretion, in addition to inactivating the hormone. In fact, variation in the rate of excretion during development appears to be an important factor in determining the hormone titer. Furthermore, hormone inactivation by the gut may be important in protection of the insect from any ingested phytoecdysteroids (see below). In closed stages of insects, where excretion is impossible (egg and pupae), irreversible inactivation of ecdysteroids is important, with metabolites accumulating in the gut (Koolman and Karlson, 1985; Isaac and Slinger, 1989; Lafont and Connat, 1989).

A comparative study of the metabolism of E and 20E in representatives of arthropods, mollusks, annelids, and mammals has led to the conclusion that the metabolic pathways differ strongly between species and that each class has evolved specific reactions (Lafont *et al.*, 1986).

3.3.5.3.2.1. Conjugates and overall metabolism Aspects of conjugate formation will be considered initially, since such compounds feature prominently in the metabolism and inactivation of ecdysteroids in immature stages of most insect species. Early studies on enzymatic aspects of ecdysteroid conjugation/hydrolysis have been reviewed (Weirich, 1989). Originally, the identification of various conjugated ecdysteroid inactivation products (e.g., 3-acetylecdysone 2-phosphate), together with the ecdysteroid 26-oic acids from developed eggs of locusts before hatching facilitated elucidation of inactivation pathways in other systems (Lagueux *et al.*, 1984; Rees and Isaac, 1984). In fact, in larval stages of locusts, the inactivation pathways (Gibson *et al.*, 1984; Modde *et al.*, 1984) proved to be very similar to the embryonic routes (see **Figure 16**), with pathways in other species having much in common (Lafont and Connat, 1989). Some features of ecdysteroid metabolic pathways in various stages of a few species that have been reported since the first edition in 1985 will be considered initially. In *Manduca*, when labeled C was injected into 5th instar larvae and the metabolites isolated from day 8 pupae, the predominant ecdysteroid metabolites were 20E, 20,26-dihydroxyecdysone, 20-hydroxyecdysonoic acid, and 3-epi-20-hydroxyecdysonoic acid. Smaller amounts occurred as conjugates (phosphates) of 26-hydroxyecdysone, 3-epi-20-hydroxyecdysone, 20, 26-dihydroxyecdysone, and its 3α-epimer (Lozano *et al.*, 1988a, 1988b). At various stages throughout pupal–adult development, the predominant metabolites were 3-epi-20-hydroxyecdysonoic acid and the phosphate conjugates of 3-epi-20-dihydroxyecdysone (Lozano *et al.*, 1989).

In feeding last larval stage of another lepidopteran, *Pieris brassicae*, injected 20E was converted primarily into 20-hydroxyecdysonoic acid, 3-dehydro-20-hydroxyecdysone, and 3-epi-20-hydroxyecdysone 3-phosphate. Use of E as substrate gave the same metabolites, together with ones lacking the 20-hydroxyl group (Beydon *et al.*, 1987). Similarly, in *P. brassicae* eggs, [^{3}H]-ecdysone metabolism is similar to that in larvae and pupae viz. hydroxylation at C_{20} and C_{26}, with further oxidation to ecdysteroid 26-oic acids. Injection of [^{3}H]-cholesterol into female pharate adults indicated that the egg ecdysteroids/metabolites consisted of 20-hydroxyecdysonoic acid, ecdysonoic acid, 20E, and E (Beydon *et al.*, 1989). In another lepidopteran, the tobacco budworm, *Heliothis virescens*, incubation of testes with labeled E yielded a range of products including 20, 26-dihydroxyecdysone, 3-epi-20-hydroxyecdysone, 20E, and highly polar metabolites (Loeb and Woods, 1989).

In female adults of the cricket, *Gryllus bimaculatus*, injected [^{3}H]-ecdysone was converted into at least 24 metabolites, the highest number being in the gut and feces, and included 26-hydroxyecdysone and 14-deoxyecdysone amongst the free ecdysteroids. In addition, polar (phosphate) and apolar (fatty acyl) conjugates were also observed. Following feeding of [^{3}H] ecdysone, most of the label remained within the gut and was excreted within 48 h, with 14-deoxyecdysone being a major metabolite (Thiry and Hoffmann, 1992). Both apolar and polar ecdysteroid conjugates are widely distributed in tissues of males of this species (Hoffmann and Wagemann, 1994). In vitellogenic females of *Labidura riparia* (Dermaptera), [^{3}H] 20-E was metabolized primarily through conjugation, in particular acetylation at C_3 and phosphate ester formation at C_2 (Sayah and Blais, 1995).

Incubation of midgut cytosol of *Manduca*, where prominent 3-epimerization of ecdysteroid occurs, with [^{3}H]-ecdysone and Mg^{2+}/ATP, results in detection of four E phosphoconjugates and two 3-epiecdysone phosphoconjugates (Weirich *et al.*, 1986). ATP- and Mg^{2+}-dependent ecdysteroid phosphotransferase activities have been demonstrated in cytosolic extracts of ovaries and fat body from mature female pupae of *B. mori* (Takahashi *et al.*, 1992). The midgut cytosol of the cotton leafworm, *S. littoralis*, contains Mg^{2+}/ATP-dependent ecdysteroid 2- and 22-phosphotransferase activities, with a predominance of the former (Webb *et al.*, 1995). The

phosphotransferase activities were high early in the final larval instar and then declined. The relatively high K_M value (21 μM) of the E 2-phosphotransferase (Webb *et al.*, 1996), together with its expression during the feeding period when the hemolymph ecdysteroid titer is low, may suggest that these phosphotransferase enzymes are involved in inactivation of any dietary ecdysteroids.

The enzymes catalyzing formation of E 3-acetate and its phosphorylation in production of 3-acetylecdysone 2-phosphate have been characterized in larval tissues of *Schistocerca*. 3-Acetylation of E and 20E was characterized in gastric caeca from final larval instar *S. gregaria*, since high activity occurred in that tissue. The microsomal enzyme had a somewhat stronger affinity for 20E (K_M 53.5 μM) than E (71 μM) and utilized acetyl coenzyme A, but not acetic acid, as cosubstrate, indicating that the enzyme is an acetyl coenzyme A (CoA): ecdysteroid acetyltransferase and not a hydrolase. Furthermore, esterification of E was not observed when long-chain fatty acylCoA derivatives were substituted as cosubstrates (Kabbouh and Rees, 1991b).

In final instar *S. gregaria* larvae, ATP: E 3-acetate 2-phosphotransferase activity was low in gastric caeca and gut, but was somewhat higher in fat body than in Malpighian tubules. Thus, the soluble fat body enzyme (*ca.* 45 kDa) was characterized. The Mg^{2+}/ATP dependent phosphotransferase utilized E 3-acetate as the preferred substrate (K_M 10.5 μM), with no significant phosphorylation of E and E 2-acetate. The physiological significance of the increase in phosphotransferase activity during the second half of the instar, well before the rise in ecdysteroid titer, is unclear (Kabbouh and Rees, 1993).

In some lepidopteran species, e.g., *Heliothis armigera* (cotton bollworm, Robinson *et al.*, 1987) and *Heliothis virescens* (cotton budworm, Kubo *et al.*, 1987), a major fate of ingested ecdysteroids is formation of 22-fatty acyl esters in the gut for fecal excretion. Characterization of the ecdysteroid-22-*O*-acyltransferase activity in crude homogenates of midgut from *H. virescens* has shown that the enzyme can use fatty acyl CoA as cosubstrate, but not phosphatidylcholine or free fatty acid, indicating that the enzyme differs appreciably from the cholesterol acyltransferase, where all such cosubstrates can be utilized (Zhang and Kubo, *et al.*, 1992a). Furthermore, unlike the situation for the latter enzyme, divalent cations inhibit the ecdysteroid acyltransferase. Subsequently, it has been demonstrated that the ecdysteroid 22-*O*-acyltransferase is located in the plasma membrane of the gut epithelial cells (gut brush border membrane; Kubo *et al.*, 1994). The acyltransferase was active only during feeding stages, its activity decreased as the larvae became committed to pupation and was not enhanced by feeding ecdysteroids to the fifth instar larvae (Zhang and Kubo *et al.*, 1992b). It has been suggested that dietary phytoecdysteroid detoxification is the major function of the acyltransferase (Zhang and Kubo, 1992b, 1994). In both *H. virescens* and *B. mori*, injected E was converted into 20E, 26-hydroxyecdysone, and 20, 26-dihydroxyecdysone, which was oxidized to 20E 26-oic-acid for excretion. These transformations also occurred in the case of ingested E in these species, but as already seen in *H. virescens*, an additional prominent route involved E–22-O-acyl ester formation, which was largely excreted. In contrast, in *B. mori*, the latter pathway was replaced by formation of 3-epi-E and a polar conjugate tentatively identified as the sulfate, which was excreted, in the case of ingested E (Zhang and Kubo, 1993). In the tomato moth, *Lacanobia overacea*, and the cotton leafworm, *Spodoptera littoralis*, the situation is similar to that in *H. virescens*, where injected/endogenous ecdysteroids undergo conversion into 20-hydroxyecdysonoic acid, with ingested ecdysteroids undergoing detoxification yielding apolar 22-fatty acyl esters (Blackford and Dinan, 1997a; Blackford *et al.*, 1997). Surprisingly, the Death's head hawkmoth, *Aclerontia atropos*, is unaffected by dietary 20E, which it excretes in an unmetabolized form (Blackford and Dinan, 1997b). Interestingly, in four other Lepidoptera (*Aglais urticae, Inachis io*, *Cynthia cardini*, and *Tyria jacobaeae*) ingested and injected 20E followed the same fate, with polar compounds being prominent and no detectable formation of 22-fatty acyl esters (Blackford and Dinan, 1997c).

In adult *Drosophila melanogaster*, following injection of [^{3}H]-E, E-22-fatty acyl esters were the major metabolites, followed by 3dE, 26-hydroxyecdysone, ecdysonoic acid, 20-hydroxyecdysone, and E 22-phosphate (Grau and Lafont, 1994a; Grau *et al.*, 1995). 20E was metabolized in a similar manner (Grau and Lafont, 1994a). The E-22-phosphate was produced in the ovaries, whereas E was efficiently converted into 3DE and ecdysone 22-fatty acyl esters by gut/Malpighian tubule complexes (Grau and Lafont, 1994b). In third instar *D. melanogaster* larvae, although E metabolism proceeds through different pathways including C_{20} hydroxylation, C_{26} hydroxylation, and oxidation to 26-oic acids, C_3 oxidation and epimerization followed by conjugation, 3-dehydroecdysteroids are the major metabolites, with C_3 oxidation occurring in various tissues (Sommé-Martin *et al.*, 1988).

3.3.5.3.2.2. 26-Hydroxylation and ecdysonoic acid formation Ecdysonoic acid and 20-hydroxyecdysonoic acid were originally identified from developing eggs of *Schistocerca*, pupae of *Spodoptera* (Isaac *et al*., 1983), and *Pieris*, where their formation has been shown to occur in several tissues (Lafont *et al*., 1983). Since that time, it has become apparent that 26-oic acid formation is a widespread and prominent pathway of ecdysteroid inactivation, as alluded to in several studies considered above.

It has been shown that administration of E, 20E, or an ecdysteroid agonist, RH-5849, to last-instar larvae of the cotton leafworm, *S. littoralis*, leads to induction of ecdysteroid 26-hydroxylase activity in fat body mitochondria (Chen *et al*., 1994b). This induction occurred in both early last instar larvae and in older larvae that had been head-ligated to prevent the normal developmental increase in E 20-monooxygenase activity. The induction of hydroxylase activity requires both RNA and protein synthesis. E-26-oic acid and a compound tentatively identified as the 26-aldehyde derivative of E were also formed from E in the RH 5949-induced systems. Direct demonstration in a cell-free system of the conversion of 26-hydroxyecdysone into the aldehyde and the corresponding 26-oic acid (ecdysonoic acid), established the following inactivation pathway: ecdysteroid → 26-hydroxyecdysteroid → ecdysteroid 26-aldehyde → ecdysteroid 26-oic acid. Whether these three reactions are catalyzed by a single enzyme (as is the case of rabbit liver cytochrome P450 CYP27, which catalyzes the complete conversion of 3α,7α,12α-trihydroxy-5β-cholestane into 3α,7α,12α-trihydroxy-5β-cholestanoic acid (see Betsholtz and Wikvall, 1995) remains an open question.

Induction of the 26-hydroxylase activity might be expected to result from enhanced cytochrome P450 gene transcription and protein synthesis (Chen *et al*., 1994b). Similarly, both 20E and RH-5849 caused RNA- and protein-synthesis-dependent induction of ecdysteroid 26-hydroxylase activity in midgut mitochondria and microsomes in *Manduca* (Williams *et al*., 1997). This induction of an ecdysteroid inactivation pathway (and others, see following section) by 20E and RH-5849 is reminiscent of the regulation of vitamin D inactivation in vertebrates where 1α,25-dihydroxyvitamin D_3 stimulates its own degradation by induction of a vitamin D response element to initiate degradation to excretory metabolites (see Williams *et al*., 1997 for references). However, the possibility cannot be discounted that at least some of the observed induction events may be indirect. Evidence has been furnished that the 26-hydroxylase activity is a typical NADPH-requiring cytochrome P450-dependent monooxygenase that is sensitive to inhibition by CO and imidazole/triazole-based fungicides (Kayser *et al*., 1997; Williams *et al*., 2000). Furthermore, indirect evidence suggested that the *Manduca* mitochondrial and microsomal 26-hydroxylases could exist in a less active dephosphorylated state or more active phosphorylated state (Williams *et al*., 2000). Interestingly, long-term culture of a *Chironomus tentans* (Diptera) cell line in the presence of 20E resulted in selection of subclones that are resistant to the steroid, but respond normally to the agonist, tebufenozide (RH-5992) (see **Chapter 3.4**). Evidence was obtained that ecdysteroid resistance of the cell clones is due to high metabolic inactivation of the hormone by 26-hydroxylation (Kayser *et al*., 1997). In this cell system, 20,26-dihydroxyecdysone is further metabolized to two compounds that are slowly interconvertible geometrical isomers, which presumably arise from hemiacetal formation between the 26-aldehyde and the 22*R*-hydroxyl groups to yield a tetrahydropyrane ring in the side chain (Kayser *et al*., 2002). Induction of ecdysteroid 26-hydroxylase by the agonists RH-5849, RH-5992, and RH-0345 appears universal in lepidopteran species that show susceptibility to the agonists (Williams *et al*., 2002). It appears that the more potent ecdysteroid agonists in Lepidoptera, RH-5992, and RH-0345 show in general a greater induction of 26-hydroxylase than does RH-5849. Feeding RH-5849 to the dipteran *Musca domestica* results in induction of an ecdysteroid phosphotransferase. The low toxicity of the ecdysteroid agonists in orthopteran and coleopteran orders also correlates with a lack of induction of ecdysteroid 26-hydroxylase activity. In fact, it has been proposed that in species where ecdysteroid agonists are effective in stimulating an untimely premature molt, a response to a state of apparent hyperecdysonism elicited by the agonists is induction of enzymes of ecdysteroid inactivation (Williams *et al*., 2002) (see **Chapter 3.4**).

3.3.5.3.2.3. 3-Epimerization An oxygen and NAD(P)H-dependent "E epimerase" activity was originally reported in *Manduca* midgut cytosol which irreversibly converted E into its 3α-isomer (3-epiecdysone; Nigg *et al*., 1974; Mayer *et al*., 1979). Subsequently, this transformation has been shown to occur via the oxygen-dependent E oxidase catalyzed formation of 3DE, which is then irreversibly reduced to 3-epiecdysone, catalyzed by NAD(P)H-dependent 3-dehydroecdysteroid 3α-reductase (**Figure 18**) (*Pieris*, Blais and Lafont, 1984; *Spodoptera*, Milner and Rees, 1985; *Manduca*, Weirich, 1989).

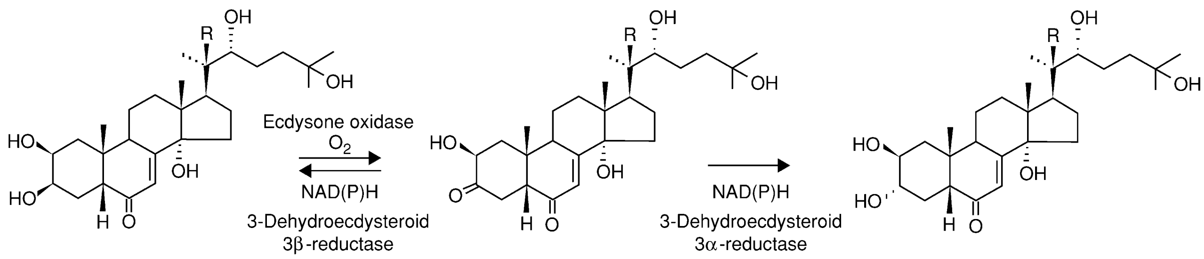

Figure 18 Enzymatic interconversion of 3β-ecdysteroids, 3-dehydroecdysteroids, and 3α-ecdysteroids. R = H: Ecdysone (metabolites); R = OH: 20-hydroxyecdysone (metabolites). (Modified from Rees, H.H. **1995**. Ecdysteroid biosynthesis and inactivation in relation to function. *Eur. J. Entomol. 92*, 9–39.)

The 3-epiecdysteroid product may also undergo phosphoconjugation. However, many tissues also contain an NAD(P)H-dependent 3-dehydroecdysteroid 3β-reductase, which reduces the 3DE back to E (see Lafont and Koolman, 1984); the exact significance of this apparent futile cycle is unclear. The foregoing pathways occur with E and 20E and have been reviewed (Lafont and Koolman, 1984; Koolman and Karlson, 1985; Thompson *et al.*, 1985a; Weirich, 1989; Rees, 1995). It is apparent from the foregoing sections of this chapter that 3-epiecdysteroid formation is a widespread ecdysteroid metabolic pathway amongst species, with the 3-dehydroecdysteroid 3α-reductase being apparently restricted to gut tissues. 3-Epiecdysteroid formation is certainly emphasized in Lepidoptera.

The kinetic properties and developmental expression of E oxidase, 3-dehydroecdysteroid 3α-reductase and 3β-reductase enzymes from midgut cytosol of *Manduca* (Weirich *et al.*, 1989, 1991, 1993) and *Spodoptera* have been investigated (Webb *et al.*, 1995, 1996). In the former species, the larval midgut was the only organ exhibiting substantial specific activities of E oxidase and 3α-reductase, with both activities increasing up to the seventh day after ecdysis (Weirich *et al.*, 1989). Hemolymph and fat body had only moderate to high 3β-reductase and low E oxidase activities, whereas the epidermis did not contain significant activities of any of the enzymes. Thus, apparently, only the larval midgut has a role in the inactivation of ecdysteroids by 3-epimerization in *Manduca*.

It has been shown that administration of the hormone agonist, RH5849, but not of 20E, to *Manduca* results in RNA- and protein-dependent induction of the midgut cytosol E oxidase and 3-epiecdysone phosphotransferase activities (Williams *et al.*, 1997). Clearly, elucidation of the significance of these results requires further work.

Ecdysone oxidase from *Calliphora* was amongst the first enzymes catalyzing ecdysteroid transformations to be investigated extensively (Koolman, 1978; Koolman and Karlson, 1978; Koolman, 1985) and has been purified considerably (Koolman and Karlson, 1978). In *Calliphora vicina* also, injected 3DE is rapidly reduced *in vivo*, but relative formation of E and 3-epiecdysone cannot be ascertained since the TLC fractionation system employed lacks resolution (Karlson and Koolman, 1973). The reaction catalyzed by E oxidase (EC 1.1.3.16) may be written as:

$$E + O_2 = \text{3-dehydroecdysone} + H_2O_2$$

The enzyme would be expected to possess a prosthetic group, but none has been identified so far. E oxidase efficiently oxidizes a number of ecdysteroids, but not 22,25-dideoxyecdysone nor cholesterol (Koolman and Karlson, 1978; Koolman, 1985). E oxidase represents the only oxidase in eukaryotic animals known to catalyze oxygen-dependent oxidation of steroids; in contrast, oxidation of steroids in vertebrates occurs via NAD(P) $^+$-linked dehydrogenases.

The native enzyme from *Calliphora* has an apparent molecular mass of approximately 240 kDa (Koolman, 1985). However, native E oxidase purified from midgut cytosol of *Spodoptera* might be a trimer (approximately 190 kDa), since the apparent Mr of the oxidase subunit was 64 kDa by SDS-PAGE (Chen *et al.*, 1999a). The latter was corroborated by cloning the cDNA (2.8 kb) encoding a 65 kDa protein (Takeuchi *et al.*, 2001). Northern blotting demonstrated that the mRNA transcript was expressed in midgut during the prepupal stage of the last larval instar at a time corresponding to an ecdysteroid titer peak. Conceptual translation of the cDNA followed by data base searching indicated that the enzyme is an FAD flavoprotein that belongs to the glucose-methanol-choline oxidoreductase superfamily. Injection of the agonist, RH-5992, induced the transcription of E oxidase, suggesting that it is an ecdysteroid responsive gene. The gene encoding the enzyme consists of five exons and

sequences similar to the binding motifs for Broad-Complex and FTZ-F1 occur in the 5′ flanking region, consistent with ecdysteroid regulation. Southern blotting indicated that E oxidase is encoded by a single-copy gene.

Interestingly, the entomogenous fungus, *Nomuraea rileyi*, inhibits molting of its host, *B. mori*, by production of an enzyme that oxidizes the C_{22} hydroxyl group of hemolymph ecdysteroids (Kiuchi *et al.*, 2003). Whether this enzyme is an oxidase or an $NAD(P)^+$-dependent dehydrogenase has not been established.

One major 3-dehydroecdysteroid 3α-reductase (active with both NADPH and NADH) together with three major 3-dehydroecdysteroid 3β-reductases (active only with NADPH as cosubstrate) have been fractionated from *Manduca* midgut cytosol (Weirich and Svoboda, 1992). In the case of *Spodoptera*, two forms of 3-dehydroecdysone 3α-reductase have been observed during purification, a 26 kDa form that may be a trimer with an apparent Mr of approximately 76 kDa and a second 51 kDa form that appears to be a monomer by gel filtration (Chen *et al.*, 1999a). The cDNA (1.2 kb) encoding the 26 kDa protein has been cloned and Northern blotting showed that the mRNA transcript was expressed in Malpighian tubules during the early stage of the last larval instar (Takeuchi *et al.*, 2000). Conceptual translation of the cDNA followed by database searching revealed that the enzyme belongs to the Short-chain-Dehydrogenases/Reductases (SDR) superfamily. Furthermore, the enzyme is a novel eukaryotic 3-dehydrosteroid 3α-reductase member of that family, whereas vertebrate 3-dehydrosteroid 3α-reductases belong to the Aldo-keto Reductase (AKR) superfamily. Surprisingly, no similarity was observed between the 3-dehydroecdysone 3α-reductase and a reported 3-dehydroecdysone 3β-reductase from the same species (Chen *et al.*, 1999b), which acts on the same substrate and belongs to the AKR family.

As alluded to earlier, 3-dehydroecdysteroid 3β-reductase activity has been demonstrated in the cytosol of various tissues of many species. In addition, hemolymph 3-dehydroecdysteroid 3β-reductase is involved in reduction of the 3DE produced by prothoracic glands of many lepidopterans (see Section 3.3.4.2.; Warren *et al.*, 1988b; Sakurai *et al.*, 1989; Kiriishi *et al.*, 1990).

Hemolymph NAD(P)H-dependent 3-dehydroecdysone 3β-reductase activity has been shown to undergo developmental fluctuation in several species, exhibiting high activity at the time of the peak in ecdysteroid titer near the end of the last larval instar (*Manduca*, Sakurai *et al.*, 1989; *Spodoptera*, Chen *et al.*, 1996; *Periplenta americana*, Richter *et al.*, 1999). In *P. americana*, some enzyme is located on the outer surface of the prothoracic gland cells as well. The exact source of the hemolymph 3-dehydroecdysone 3β-reductase and the mechanism regulating its expression during development have not been elucidated. The 3β-reductase has a wide tissue expression (*Pieris*, Blais and Lafont, 1984; European corn borer, *Ostrinia nubilalis*, Gelman *et al.*, 1991; *Bombyx*, Nomura *et al.*, 1996), including embryonated eggs of the gypsy moth, *Lymantria* (Kelly *et al.*, 1990). Of significance to ecdysteroid biosynthesis is the demonstration that various 3-dehydroecdysteroid precursors may be reduced to the corresponding 3β-hydroxy compounds in prothoracic glands and follicle cells of *Locusta* (Dollé *et al.*, 1991; Rees, 1995).

The 3-dehydroecdysteroid 3β-reductases have been purified from hemolymph of *Bombyx* (Nomura *et al.*, 1996) and *Spodoptera* (Chen *et al.*, 1996), demonstrating that the native enzyme is a monomer of Mr of approximately 42 kDa and 36 kDa, respectively. In the case of both enzymes, a lower K_m was observed with NADPH than with NADH as cosubstrate (*B. mori*, 0.90 μM versus 5.4 μM; *S. littoralis*, 0.94 μM versus 22.8 μM). Kinetic analysis of the *S. littoralis* hemolymph 3β-reductase, using either NADPH or NADH-as cofactor, revealed that the enzyme exhibits maximal activity at low 3DE substrate concentrations, with a drastic inhibition of activity at higher concentrations (>5 μM). Similar substrate inhibition was observed for the cytosolic NADPH-dependent 3-dehydroecdysone 3α-reductase of *Manduca* midgut which showed apparent 3DE substrate inhibition above 10 μM (Weirich *et al.*, 1989). Although the K_M for the *S. littoralis* hemolymph 3-dehydroecdysone 3β-reductase has not been determined due to the substrate inhibition, it is conceivable that the K_M value could be less than 5 μM. The results suggest that the 3β-reductase has a high-affinity (low K_M) binding site for the 3-dehydroecdysteroid substrate, together with a lower affinity inhibition site (Chen *et al.*, 1996). Cloning of the full-length 3-dehydroecdysone 3β-reductase cDNA from *S. littoralis* and conceptual translation yield a protein with a predicted Mr of 39 591 of which the first 17 amino acids appear to constitute a signal peptide to yield a predicted Mr for the mature protein of 37 689 (Chen *et al.*, 1999b), which agrees with the approx. Mr (36 kDa) of the purified protein on SDS-PAGE. Similarly, database searching suggested that the enzyme is a new member of the third (AKR) superfamily of oxidoreductases.

Northern blot analysis revealed that highest expression is detected in Malpighian tubules, followed

by midgut and fat body, with low-level expression in hemocytes and none detectable in central nervous system. Surprisingly, preliminary results of Western blotting experiments revealed 3β-reductase detection in hemolymph and hemocytes, with little in midgut and none in Malpighian tubules, in agreement with the results for *B. mori* (Nomura *et al*., 1996). This suggests that selective translation of mRNA may contribute to regulation of expression of 3-dehydroecdysteroid 3β-reductase (Chen *et al*., 1999b). The developmental profile of the mRNA revealed that the gene is only transcribed in the second half of the sixth instar essentially at the time of increasing enzymatic activity and ecdysteroid titer. Thus, it appears that the change in 3β-reductase activity is, at least in part, regulated by gene expression at the transcriptional level, although posttranscriptional regulation may also be important in certain tissues. Southern analysis indicates that the 3-dehydroecdysone 3β-reductase is encoded by a single gene, which probably contains at least one intron (Chen *et al*., 1999b). Recently, a gene encoding a protein that shows 42.5% identity to *S. littoralis* 3-dehydroecdysteroid 3β-reductase has been cloned from the cabbage loofer, *Trichoplusia ni* and the protein has been shown to possess low 3β-reductase activity (Lundström *et al*., 2002). Northern blotting has indicated that highest expression of the gene is detected in fat body, the expression being highly induced after bacterial challenge. However, by immunohistochemistry, the protein was localized exclusively in the epidermis and the cuticle, but its significance is unclear.

3.3.5.3.2.4. 22-Glycosylation The formation of 26-hydroxyecdysone 22-glucoside in late embryos of *Manduca* has already been alluded to (Thompson *et al*., 1987a).

In the baculovirus, *Autographa californica* nuclear polyhedrosis virus, expression of the *egt* gene produces UDP-glycosyl transferase, which apparently inactivates the host ecdysteroids by catalyzing production of ecdysteroid 22-glycoside. Thus, *egt* gene expression allows the virus to interfere with insect development by blocking molting in infected larvae of the fall armyworm, *Spodoptera frugiperda* (O'Reilly and Miller, 1989; O'Reilly *et al*., 1991). Although kinetic analysis indicates that the ecdysteroid UDP-glucosyltransferase (EGT) has broadly similar specificities for UDP-galactose and UDP-glucose (Evans and O'Reilly, 1998), there is evidence that *in vivo*, ecdysteroids are conjugated with galactose (O'Reilly *et al*., 1992; review: O'Reilly, 1995). EGT appears to be an oligomer of 3–5 subunits (Mr approx 56 kDa) and, surprisingly, E seems to be the optimal substrate, whereas 3DE is seven times less favorable, with 20E being conjugated very poorly, more than 34 times less readily than 3DE (Evans and O'Reilly, 1998). The physiological significance of this finding is uncertain. Analogous EGT enzymes and mechanisms have been established for the gypsy moth *Lymantria* nuclear polyhedrosis virus (Park *et al*., 1993; Burand *et al*., 1996), *Epiphyas postvittana* nucleopolyhedrovirus (Caradoc-Davies *et al*., 2001), and *Mamestra brassicae* multinucleocapsid nucleopolyhedrovirus (Clarke *et al*., 1996).

3.3.5.3.2.5. Neglected pathways? Given the huge diversity of insects, there is no reason to consider that metabolic pathways are restricted to those-described above. A few examples will illustrate that the story is not finished:

- Side chain cleavage between C_{20} and C_{22} resulting in the formation of poststerone was described long ago in *Bombyx* by Hikino *et al.* (1975); moreover, other experiments have demonstrated the ability of certain insects to produce C_{21} steroids from cholesterol in exocrine glands of aquatic beetles (Schildknecht, 1970) and also ovaries of *Manduca* (Thompson *et al*., 1985c), providing the evidence for a desmolase activity in some insect species at least. The fact that available [^{3}H]-ecdysteroids are labeled on the side chain has precluded further analysis of this problem, as the resulting poststerone would not be labeled and the radioactivity would become "volatile". This problem awaits reexamination when nuclear labeled ecdysteroids are available.
- Minor ecdysteroids have been isolated from *Bombyx* that bear an –OH group in positions 16β (Kamba *et al*., 2000b) or 23 (Kamba *et al*., 2000a), which indicates that during some developmental stages at least (here in adults) additional CYPs must be active.
- 14-Deoxy metabolites of E and 20E have been identified in *Gryllus bimaculatus* feces, and their formation is probably due to bacterial metabolism in the insect gut (Hoffmann *et al*., 1990).
- Labeling studies with *Drosophila* adults have shown very complex patterns that include some as yet unidentified metabolites (Grau and Lafont, 1994a, 1994b). Their chromatographic behavior is consistent with the presence of one additional –OH group in position 11β (?), but positions 16β and 23 as observed in *Bombyx* (see above) are also plausible.
- Finally, it should be noted that sulfate conjugates, although never isolated as endogenous metabolites, can be formed *in vitro* by insect/tissue homogenates incubated with ecdysteroids and

a sulfate donor (e.g., *Prodenia eridania* gut: Yang and Wilkinson, 1972; *Aedes togoi* whole larvae/pupae/adult: Shampengton and Wong, 1989; *Sarcophaga peregrina* fat body: Matsumoto *et al.*, 2003). In *Sarcophaga*, a 43 kDa protein responsible for this reaction was purified by affinity chromatography on a 3′-phosphoadenosine 5′-phosphate (PAP)-agarose column (Matsumoto *et al.*, 2003). However, the physiological significance of such activities *in vivo* in ecdysteroid metabolism remains to be firmly established, since it is conceivable that the activity observed might be ascribed to another primary activity, with low specificity for ecdysteroids.

3.3.6. Some Prospects for the Future

3.3.6.1. Evolution and Appearance of Ecdysteroids

Zooecdysteroids are not restricted to arthropods. Trace amounts of E, 20E, and other ecdysteroids have been detected by HPLC-immunoassays or GC-MS in annelids, nematodes, helminths, and mollusks (Spindler, 1988; Franke and Käuser, 1989; Barker *et al.*, 1990). More recently, ecdysteroids were also found in nemerteans (Okazaki *et al.*, 1997). It must be emphasized that at the moment there is no evidence that these animals are able to produce ecdysteroids themselves, as they seem to lack some key biosynthetic enzymes, a conclusion based on metabolic studies performed with biosynthetic intermediates efficiently converted in arthropods (**Table 8**, Lafont *et al.*, 1995; Lafont, 1997). An evolutionary scenario (see **Chapter 3.6**) has been proposed for the progressive appearance of enzymes, which resulted in an increasing number of hydroxyl groups on the sterol molecule (the last ones being the three mitochondrial enzymes, i.e., the 22-, 2-, and the 20-hydroxylases). A similar phylogenetic emergence seems to have operated in the case of vertebrate-type steroid hormones (Bolander, 1994).

Several findings, however, do not fit with this scheme. In particular, large amounts of ecdysteroids have been isolated from Zoanthids (e.g., Sturaro *et al.*, 1982; Suksamrarn *et al.*, 2002) and even from various sponges (Diop *et al.*, 1996; Cafieri *et al.*, 1998; Costantino *et al.*, 2000). The large amounts seem to preclude a hormonal role and rather fit with an allelochemical (protective) role, perhaps against predation, as in the case of pycnogonids (Tomaschko, 1995). In the case of Zoanthids, it is conceivable that ecdysteroids arise from their food (e.g., copepods), but this does not seem so evident in the case of sponges, which are expected to feed on bacteria, protozoa, or dissolved matter, none of

Table 8 Presence/absence of some key hydroxylases involved in ecdysteroid biosynthesis and/or metabolism in invertebrates

(Eds.), Recent Advances in Insect Biochemistry and Molecular Biology. University of Nagoya Press, Nagoya, pp. 45–91.

which are known to contain ecdysteroids. This awaits additional experiments to establish whether or not sponges are able to produce ecdysteroids themselves. It should be noted that sponges also contain an incredible number of steroids (Aiello *et al.*, 1999), including steroidal $\Delta^{4,7}$-3,6-diketones (Malorni *et al.*, 1978) or 4,6,8-triene-3-ones (Kobayashi *et al.*, 1992), which resemble putative ecdysteroid precursors (Grieneisen *et al.*, 1991; Grieneisen, 1994; Gilbert *et al.*, 2002). We expect that molecular approaches will allow a search for homologs of insect biosynthetic enzymes that will provide an adequate answer to this fundamental problem in comparative endocrinology.

3.3.6.2. Biosynthetic Pathway(s)

The last 2 years have resulted in a spectacular improvement of our knowledge of ecdysteroidogenic enzymes, thanks to the *Drosophila* Halloween mutants. Up to now, however, this has only led to the characterization of enzymes involved in already identified reactions (i.e., hydroxylations at positions 25, 2, 22, and 20), due to the expression of recombinant enzymes and the determination of their catalytic activity. Whether this approach will suffice in the identification of the remaining unknown reactions (the so-called "black box") is debatable. Subsequent to the conversion of C to 7dC by the 7,8-dehydrogenase present in the ER, oxidized early intermediates do not accumulate under normal conditions. In theory we may expect to increase their

concentrations by using one (or a combination) of the following strategies: (1) the use of mutants defective in one or several terminal enzymes; (2) the use of specific inhibitors of these enzymes (Burger *et al.*, 1988, 1989; Mauvais *et al.*, 1994); or (3) the use of subcellular fractions instead of whole cells/tissues in order to have only a few biosynthetic enzymes present in the preparation. An additional technical problem to overcome will be the instability of such intermediates. This problem has already been encountered when using a tritiated $\Delta^{4,7}$-3,6-diketone (Blais *et al.*, 1996) or α-5,6-epoxy7dC (Warren *et al.*, 1995). Furthermore, recent experiments (see Section 3.3.4.2.2) suggest that the long-hypothesized, rate-limiting, mitochondrial P_{450}-mediated "black box" oxidations of 7dC, leading to the Δ^4-diketol, cannot be catalyzed by a mitochondrial P450 enzyme and may not even occur in the mitochondria. Studies implicating the mitochondria in these novel transformations employed crude membrane fractions from *Manduca* prothoracic glands (Warren and Gilbert, 1996) and there was clear evidence for the co-sedimentation of a large proportion of the microsomes with the crude mitochondrial pellet, as has been observed with other insect prothoracic gland tissues (Kappler *et al.*, 1988). However, insect peroxisomes also normally sediment with the mitochondrial pellet (Kurisu *et al.*, 2003) and mammalian peroxisomes are known to participate in the oxidation of both steroids and fatty acids (Breitling *et al.*, 2001). Thus, it is possible that the oxidation of 7dC (or 3-oxo7dC) may instead occur in this membrane-bound subcellular organelle. In addition, the peroxisome has been shown to be a target of sterol carrier protein 2 (Schroeder *et al.*, 2000). Also, at least in *Spodoptera frugiperda* cells, the organelle has been shown to be devoid of catalase activity, a normal marker enzyme in mammalian peroxisomes that acts to destroy hydrogen peroxide (Kurisu *et al.*, 2003). If a normal synthesis of hydrogen peroxide is also observed in insect peroxisomes, then the result could be an ideal source of oxygen for the hypothesized black box oxidations (Gilbert *et al.*, 2002).

Up to now, the black box has been investigated through trial-and-error experiments analyzing the metabolic fate of radiolabeled putative intermediates, but this has mainly led to the elimination of several hypotheses (Grieneisen, 1994). In an alternative strategy, the so-called "isotope trap," steroidogenic organs would be incubated with a labeled early precursor in the presence of an excess of an unlabeled putative downstream intermediate. If the latter is indeed an intermediate (and is stable enough to survive the incubation), it is expected to trap radioactivity due to isotopic dilution and saturation of the subsequent steps. It could also be possible to use systems capable of producing larger amounts of ecdysteroids (other than what can be achieved through the tedious dissection of thousands of prothoracic glands or ring glands), e.g., perhaps embryos or suitable plant cell or organ cell cultures, which would allow the use of precursors labeled with stable isotopes (^{2}H, ^{13}C) and subsequent NMR analysis of terminal ecdysteroid products (Fujimoto *et al.*, 1997, 2000).

Thus, the problem of the early steps remains a very open question. In addition, it may well be that different biosynthetic pathways have been developed between insects and plants (Fujimoto *et al.*, 1989, 1997; Reixach *et al.*, 1999), and perhaps also within the diverse array of insects and other arthropods. Nevertheless, the black box reactions appear to be quite specific to arthropods (and maybe a few plants). As such, they make a very appealing target for the development of novel biochemical strategies for the control of insect pests.

3.3.6.3. Additional Functions for Ecdysteroids?

We have discussed that tissues other than prothoracic glands and gonads may produce ecdysteroids, possibly as autocrine factors (see Section 3.3.4.4.2). Whatever the biosynthetic site, this corresponds to an involvement of ecdysteroids in the control of development and reproduction processes. The recent discovery of large ecdysteroid concentrations in the defensive secretions of chrysomelid beetles (Laurent *et al.*, in press) suggests a possible allelochemical role of ecdysteroids in certain cases. The situation described in chrysomelid beetles is similar to that of the pycnogonids, where ecdysteroids have been demonstrated conclusively to represent an efficient protection against predation by crabs (Tomaschko, 1995). Another example is the phytoecdysteroid accumulation by many plant species, seen as a protection against phytophagous insects (Dinan, 2001). However, it should be emphasized that previous analyses of defensive secretions of Chrysomelid beetles allowed the isolation of 2,14,22-trideoxyecdysone 3-sophorose and other ecdysteroid related compounds lacking the Δ^7 bond (Pasteels *et al.*, 1994). Thus, the story of ecdysteroid biosynthesis could turn out to be considerably more complex than it already appears to be.

Acknowledgments

René Lafont wishes to thank Dr Jean-Pierre Girault for providing the materials of Figure 2 and 5. Huw Rees is grateful to the Biotechnology and Biological

Sciences Research Council and The Leverhulme Trust for financial support of work in his laboratory, Dr Hajime Takeuchi for preparing Figures 15–18 for this review, and Dr Lyndsay Davies for help with the manuscript. James Warren would like to thank Susan Whitfield for help in preparing Figures 12 and 14a. This work was supported in part by National Science Foundation Grant IBN0130825.

3.4 Ecdysteroid Agonists and Antagonists

L Dinan, University of Exeter, Exeter, UK
R E Hormann, RheoGene Inc., Norristown, PA, USA

3.4.1. Introduction

Ecdysteroids are often regarded as the poor relatives in relation to the vertebrate steroid hormones and are in fact ignored in many reviews or textbooks on steroid hormones. Ecdysone and 20-hydroxyecdysone were identified 30 years after the vertebrate steroid hormones (Butenandt and Karlson, 1954; Huber and Hoppe, 1965) and, after a brief phase where studies on ecdysteroid regulation of puffing led the way in elucidating steroid hormone control of gene expression (Clever and Karlson, 1960; Ashburner, 1972), ecdysteroid research has returned to semiobscurity amongst the majority of biochemists and endocrinologists. This is a shame in many ways. Not only are arthropods the most numerous animals on the planet, but elucidation of the multitude of forms and developments which are ecdysteroid-dependent is an intellectual and scientific challenge (see **Chapter 3.5**). In recent years, one insect species has regained some of the lost ground, i.e., *Drosophila melanogaster*, owing to its well understood genetics, the powerful molecular biological techniques which can be applied to it and, most recently, by the complete sequencing of its genome (Adams *et al*., 2000). However, we know very little about the identities of the ecdysteroids or their metabolism during development in this species (Richards, 1981; Grau and Lafont, 1994a, 1994b) (see **Chapter 3.3**). Throughout the world there is only a handful of chemists who concern themselves with ecdysteroid chemistry. And yet, Nature has been kind to us in providing a wonderful array of ecdysteroid analogs in the form of phytoecdysteroids (Dinan, 2001). These natural analogs are an excellent starting point for structure–activity investigations of the many physiological, biochemical, or pharmacological processes affected by ecdysteroids. Ecdysteroids have considerable applied potential, ranging from the development of new, environmentally more acceptable insecticides, to gene switch elicitors and possible invertebrate endocrine disruptors. In addition to compounds with ecdysteroid-like activity, compounds which block the hormonal action of ecdysteroids (antagonists) may also have a natural role in insect–plant relationships or find application as probes for ecdysteroid-regulated gene control or even in insect pest control. The pharmacology of ecdysteroids is an almost uncharted area, but the existing data indicate intriguing prospects. Ecdysteroids provide stimulating challenges in steroid chemistry and study of their modes of action will generate new perspectives in steroid endocrinology, which will also have implications for mammalian systems. It is the purpose of this review to summarize research, especially that appearing since 1985, to reveal the diversity of analogs, strategies, and potential applications involving ecdysteroid agonists and antagonists.

3.4.2. Definitions and Conventions

The term ecdysteroid was originally defined as "all compounds structurally related to ecdysone" (Goodwin *et al*., 1978). However, Lafont and Horn (1989) differentiated between true ecdysteroids and ecdysteroid-related compounds. True ecdysteroids possess a steroid nucleus with an A/B-*cis*-ring junction and a 14α-hydroxy-7-en-6-one chromophore, irrespective of their biological activity, while ecdysteroid-related compounds do not fulfil all these criteria. Zooecdysteroids are ecdysteroids present in animals, while phytoecdysteroids are those in plants. There is overlap between these categories, since the same analog can be found in both plants and animals. The conventional numbering system for ecdysteroids (and all other steroids) is shown on the structure of the C_{29} phytoecdysteroid makisterone C in **Figure 1**. A system of standardized abbreviations for ecdysteroids has been proposed (Lafont

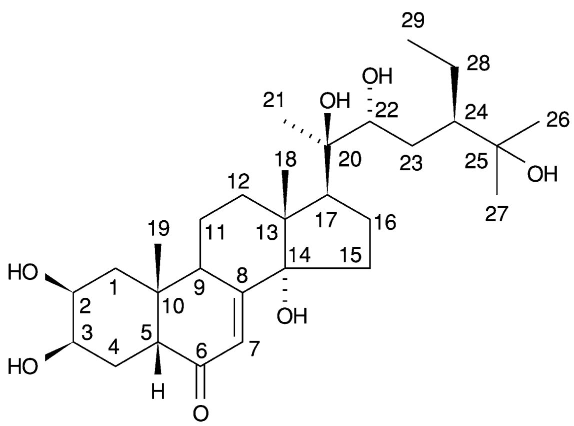

Figure 1 Structure of makisterone C showing the numbering of the carbon atoms.

et al., 1993) and is used here. We are concerned here with compounds which mimic the actions of natural ecdysteroids in specified arthropod systems (ecdysteroid agonists) or which block the actions of natural ecdysteroids in these systems (ecdysteroid antagonists). In general, we are referring to agonists and antagonists which interact with intracellular ecdysteroid receptor complexes, but it should be appreciated that there are other possible modes of action (especially for antagonists) and it is necessary to demonstrate that a particular (ant)agonist does interact with the receptor and that its affinity for the receptor should be similar to the concentration required to bring about a 50% response in the biological assay before it can be claimed as a receptor (ant)agonist. In view of the situation which prevails with certain compounds interacting with vertebrate steroid nuclear receptors, where the compound may be an agonist in one tissue, but an antagonist in another, or may be agonistic over a certain concentration range, but antagonistic over another (McDonnell *et al.*, 2002), we should be aware that a similar situation could also exist with certain ecdysteroid (ant)agonists. Such compounds would probably be called specific ecdysteroid receptor modulators (SEcRMs).

For the purposes of this review, the activity of a compound will refer to systems in which the affinity of the receptor for the compound is probably the major or only factor in determining the response. Potency will be the term used for more complicated systems, where a number of factors (i.e., penetration, sequestration, receptor affinity, metabolism, and excretion) contribute, each to a greater or lesser (and probably unknown) extent, to the magnitude of the response.

3.4.3. Studies Before 1985

3.4.3.1. Zooecdysteroids

Prior to 1985, 124 natural ecdysteroids were known, of which 27% were zooecdysteroids, 60% were phytoecdysteroids, and 13% were common to both groups (Lafont *et al.*, 2002). The zooecdysteroids fell into several categories: free ecdysteroids, polar conjugates, apolar conjugates, and ionic metabolites (ecdysonoic and 20-hydroxyecdysonoic acids). The richest sources of zooecdysteroids then known were locust (*Schistocerca gregaria* and *Locusta migratoria*) eggs, where levels reach ca. 75 $\mu g\, g^{-1}$ fresh weight (Dinan and Rees, 1981). It was generally accepted that 20-hydroxyecdysone was the hormonal molecule in invertebrate systems, although the C_{28} ecdysteroid makisterone A might replace it in systems where dealkylation of plant sterols was not fully operational (Kaplanis *et al.*, 1975; Redfern, 1984). However, the predominance of ecdysone and 2-deoxyecdysone in locust eggs and the biological activity of 3-dehydro-20-hydroxyecdysone in the induction of P1 gene transcription in fat body of *D. melanogaster* (Sommé-Martin *et al.*, 1990) indicated that other ecdysteroids might be responsible for endogenous biological activity in certain systems. The known zooecdysteroids in 1985 had mainly been isolated from insect or crustacean systems, with some compounds also being isolated and identified from coral (Guerriero and Pietra, 1985) and ecdysteroids being detected in snails (Romer, 1979), leeches (Sauber *et al.*, 1983), nematodes (Mendis *et al.*, 1983), cestodes (Mendis *et al.*, 1984), and schistosomes (Nirde *et al.*, 1983). Knowledge of the biosynthetic pathway for ecdysteroids in insects was limited to the demonstration of cholesterol as an ultimate precursor, studies on the sequence of hydroxylation reactions and studies with some stereospecifically labeled precursors (Rees, 1995). Thanks largely to the chemical synthesis of a variety of ecdysteroid analogs, the empirical understanding of ecdysteroid structure–activity studies was quite advanced in 1985 (Horn and Bergamasco, 1985). However, data had been obtained with a wide variety of *in vivo* systems, leading to a generalized understanding, which did not take account of the contributions of metabolism, sequestration, etc. to biological potency.

3.4.3.2. Phytoecdysteroids

After the almost simultaneous discovery of phytoecdysteroids by five research groups in 1966–67 (Galbraith and Horn, 1966; Nakanishi *et al.*, 1966; Heinrich and Hoffmeister, 1967; Kaplanis *et al.*, 1967; Takemoto *et al.*, 1967), a large number of analogs were identified over the next decade. Since the crystal structure of ecdysone (E) had only been finally solved in 1965 (Huber and Hoppe, 1965), the discovery of large amounts of ecdysteroids in plants was fortuitous and provided adequate amounts of certain analogs, especially 20-hydroxyecdysone (20E), for physiological and biochemical experiments on insects. Early screening studies (Imai *et al.*, 1969) indicated that ca. 6% of higher plant species contain ecdysteroids, but the concentrations vary enormously from species to species and also within the plant and during development. Ecdysteroid-containing species generally contain one or two major ecdysteroids (often 20E and polypodine B (polB)) and a plethora of minor ecdysteroids. This is reflected in the commercial price of purified ecdysteroids, since

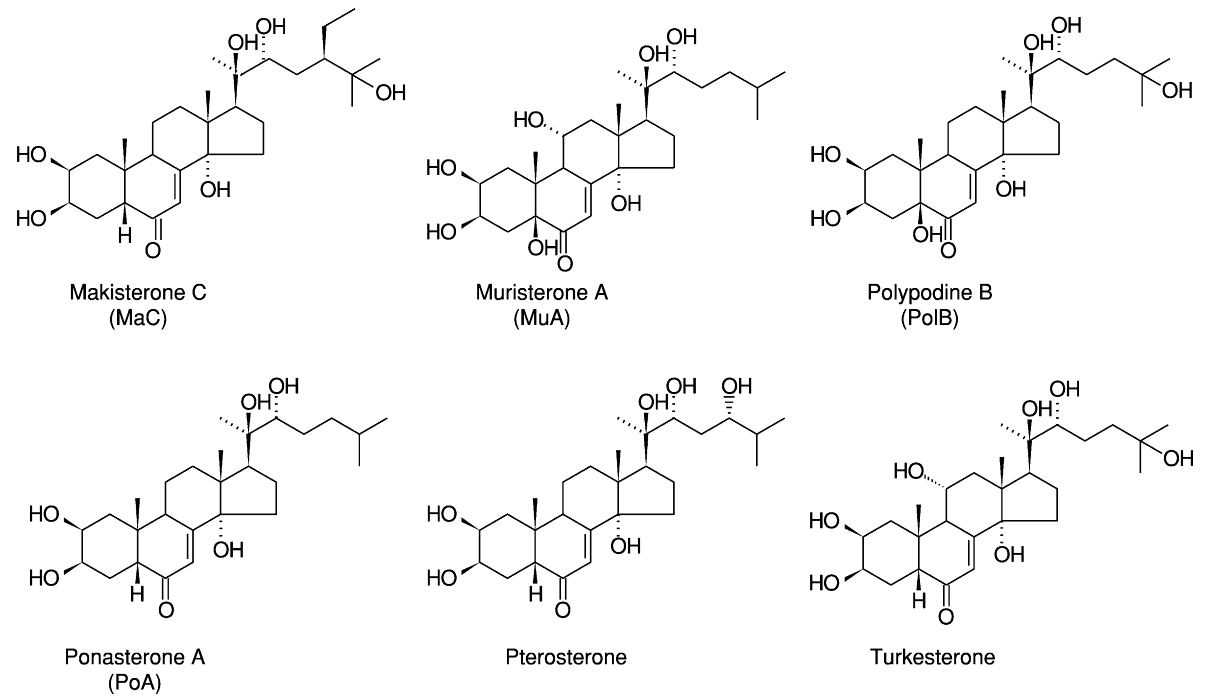

Figure 2 Commonly occurring phytoecdysteroids.

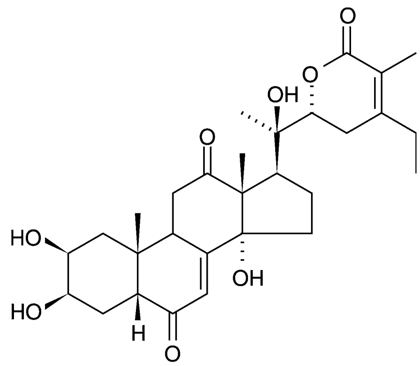
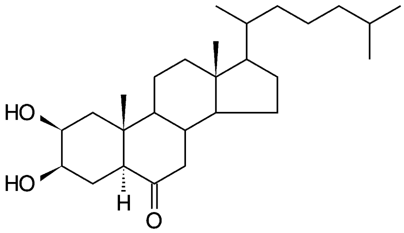
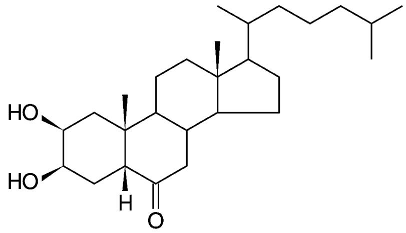
20E is the only one that is available in large amounts and at a moderate price. The structures of the most readily encountered phytoecdysteroids are given in Figure 2. It has always been appreciated that phytoecdysteroids form an excellent resource for ecdysteroid structure–activity relationship (SAR) studies, but prior to 1985 this could only be exploited in a limited way. Many of the minor ecdysteroids isolated prior to 1985 have not been isolated again since, with the result that we possess no, or very limited, information about their biological activities.

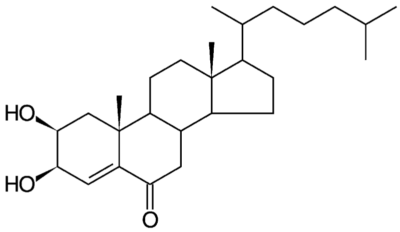
3.4.3.3. Ajugalactone

Nakanishi's group also undertook a search for "antiecdysones" in plant by using the rice stem borer *Chilo suppressalis* dipping assay to identify extracts which inhibited or delayed molting of the larvae. Ajugalactone (Figure 3) was identified as the active component from a methanol extract of *Ajuga decumbens* (Labiatae). While ajugalactone (250–500 ppm) was able to antagonize the activity of ponasterone A (PoA) (50 ppm), it had no effect against 20E (Koreeda *et al.*, 1970). The existence of a second antiecdysteroid is mentioned, which is structurally quite different and which antagonizes 20E, but not PoA. Unfortunately, no further information has been published concerning the identity or mode of action of this compound in *C. suppressalis*. In the *D. melanogaster* B_{II} bioassay, ajugalactone shows no antagonist activity against 20E or PoA (Clément *et al.*, 1993), but does possess agonist activity ($EC_{50} = 1.6 \times 10^{-7}$ M), where EC_{50} is concentration required to bring about a 50% response (Dinan *et al.*, 1999c).









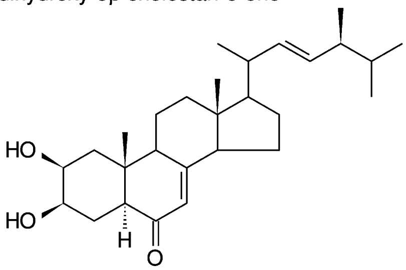


Figure 3 The structure of ajugalactone.

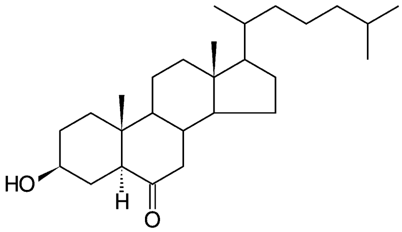
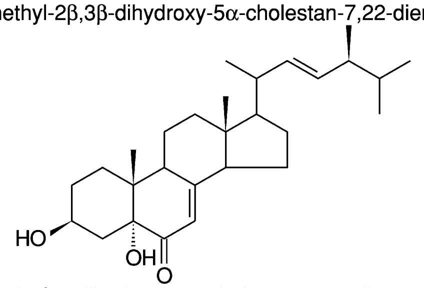
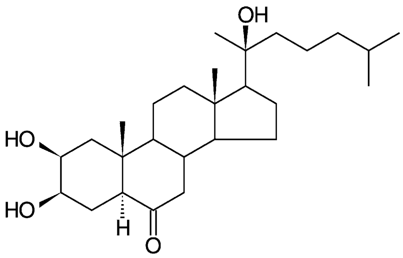
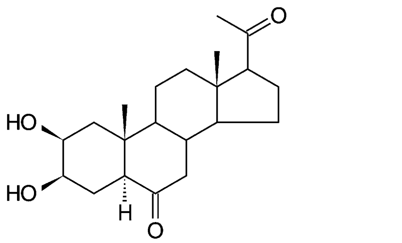
3.4.3.4. 6-Keto Steroids



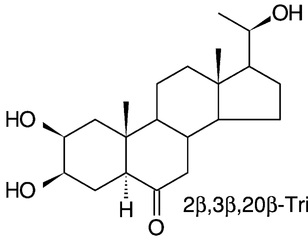


Several sterol derivatives were found to inhibit postecdysial cuticle hardening and sclerotization after injection (10–50 µg per animal) into *Pyrrhocoris apterus* (Hemiptera). The active compounds (Figure 4) all possessed a keto group at C6 and a 3β-hydroxyl. The same compounds were not active on topical application or feeding. The active compounds were believed to be ecdysteroid antagonists by the authors (Hora *et al.*, 1966; Velgová *et al.*, 1968), but no definitive evidence could be





2β,3β-Dihydroxy-5α-cholestan-6-one 2β,3β-dihydroxy-5β-cholestan-6-one



2β,3β-Dihydroxycholest-4-en-6-one 24β-methyl-2β,3β-dihydroxy-5α-cholestan-7,22-dien-6-one

3β-Hydroxy-5α-cholestan-6-one 24β-methyl-3β,5-dihydroxy-5α-cholestan-7,22-dien-6-one

2β,3β,20α-Trihydroxy-5α-cholestan-6-one 2β,3β-dihydroxy-5α-pregan-6,20-dione

2β,3β,20β-Trihydroxy-5α-pregnan-6-one

Figure 4 6-Keto steroids possessing anti-ecdysteroid activity.

provided at that time. These compounds should be reinvestigated with the currently available methods.

3.4.4. Mode of Action of Ecdysteroids

3.4.4.1. Intracellular Receptors

This topic is covered much more extensively elsewhere (see **Chapter 3.5**). Briefly, ecdysteroid intracellular receptors are members of the nuclear receptor superfamily, which have a characteristic domain structure (Kumar and Thompson, 1999). The N-terminal A/B-domain is highly variable and is associated with transcriptional activation. The C-domain is highly conserved and is involved in binding the receptor complex to specific response elements in the DNA. The D-domain is variable and represents a hinge region between the DNA-binding domain and the ligand-binding domain (E-domain).

The E-domain is not only responsible for ligand binding, but also has been implicated in receptor dimerization and interactions with other transcriptional activators. There may also be a C-terminal F-domain, which, if present, is highly variable between even closely related nuclear receptors (Kumar and Thompson, 1999). Nuclear receptors regulate gene expression as monomers or, more frequently, as dimers, either as homodimers or as heterodimers with another member of the nuclear receptor superfamily. The ecdysteroid receptor (EcR) protein forms heterodimers with Ultraspiracle (USP) (Oro *et al.*, 1990), a homolog of the vertebrate nuclear receptor RXR. Only the EcR : USP (or EcR : RXR) (Yao *et al.*, 1993) complexes are able to bind ecdysteroid with very high affinity and the presence of ecdysteroid promotes complex formation with the ecdysteroid binding to the EcR protein. For example, the affinity (K_d) for PoA of *Chilo suppressalis* EcR alone is 55 nM, which is enhanced to 1.2 nM in the presence of USP (Minakuchi *et al.*, 2003). No definitive ligand for USP has been identified, but it has been suggested that juvenile hormones (or methyl farnesoate in Crustacea) (see **Chapter 3.16**) may bind to this receptor component and modify the transactivational capacity of the complex (Jones and Sharp, 1997; Jones and Jones, 2000; Xu *et al.*, 2002).

The most extensively studied ecdysteroid receptor system in arthropods is that of *D. melanogaster*, where three isoforms (A, B1, and B2) of EcR occur (Koelle *et al.*, 1991; Talbot *et al.*, 1993). These isoforms arise through alternative promoter usage and differential splicing, resulting in different A/B-domains, but they all possess common DNA and ligand binding domains. The EcR isoforms show tissue and stage specificity. Although there is only one form of USP in *D. melanogaster*, two or more isoforms have been found in other arthropods. USP isoforms also show tissue and stage specificity (Kapitskaya *et al.*, 1996). EcR and USP gene homologs have now been characterized from a variety of arthropod species.

The biochemical characterization of intracellular ecdysteroid receptor complexes lags well behind that of vertebrate steroid hormone receptors and has been in a period of quiescence for the past decade (Luo *et al.*, 1991), as emphasis has been placed on the characterization and expression of the *EcR* and *USP* genes. The generally accepted ligand for ecdysteroid receptors in arthropods is 20E, but this does not preclude other ecdysteroids being significant at particular stages of development or in certain tissues (Wang *et al.*, 2000). *In vitro*, at least, EcR complexes recognize a wide range of ecdysteroidal and nonsteroidal analogs, as agonists or antagonists (see below).

3.4.4.2. Nongenomic Actions

In addition to the actions mediated by intracellular receptors, steroid hormones also demonstrate certain rapid (occurring within seconds) actions, which appear to be mediated by membrane effects/receptors. This is the case for vertebrate (Falkenstein *et al.*, 2000) and invertebrate (Tomaschko, 1999) steroids. One presumes that the SAR studies for ecdysteroids which have been performed to date are predominantly determined by interaction of ecdysteroids with nuclear receptors, but one should bear in mind that in certain assay systems the measured activity may be modulated by interaction with nongenomic sites.

3.4.4.3. Taste Receptors

Certain insect species have the ability to perceive ecdysteroids in their diets (Ma, 1969, 1972; Schoonhoven and Derksen-Koppers, 1973). This is probably a general phenomenon for many phytophagous insect species, since phytoecdysteroids are widespread in the plant world (Dinan, 1998). Only recently have more extensive electrophysiological studies on ecdysteroid taste receptor cells been performed (Descoins and Marion-Poll, 1999; Marion-Poll and Descoins, 2002), but very little is currently known about their specificity (Darazy-Choubaya *et al.*, unpublished data). This will clearly be an important area for future research, if ecdysteroids (or their analogs) are to be developed further as crop protection agents.

3.4.5. Strategy for the Identification of Ecdysteroid Agonists and Antagonists at Exeter University

3.4.5.1. Strategy

In 1994, as we started our search for ecdysteroid agonists and antagonists, approximately 200 zooecdysteroids and phytoecdysteroids were known as natural products (Lafont *et al.*, 2002), the diacylhydrazines had been identified as synthetic nonsteroidal agonists (Wing, 1988; Wing *et al.*, 1988), but no unambiguous antagonists were known. We reasoned that plants would be a good potential source of ecdysteroid antagonists because of their need to protect themselves against invertebrate predators. Almost as a byproduct of the research, further agonists (phytoecdysteroids and nonsteroidal compounds) could be identified. The plant natural products should come from two sources, plant extracts

and purified compounds. Several researchers generously provided samples of phytochemicals which they had isolated and identified for assessment of their activities. This approach led to the identification of withanolides (Dinan *et al*., 1996) and phenylalkanoids (Dinan *et al*., 2001a) as ecdysteroid antagonists and is facilitating SAR studies on several classes of molecules. Since there are estimated to be over 250 000 species of higher plants, it was clear from the start that a representative survey of the plant world would require the analysis of several thousand species. In the event, screening was done for just over 5000 species (ca. 2% of the total). To obtain this number of plant samples we took advantage of the British love for gardening and obtained seed samples from two commercial seed suppliers (Chiltern Seeds, Ulverston, Cumbria, UK and B&T World Seeds, Olonzac, France) and the seed-exchange scheme operated by botanical gardens throughout the world. The focus was put on extracts of seeds simply because there was no space or staff resources to grow and harvest plants of thousands of species, although, subsequently, the distribution of ecdysteroid agonists and antagonists in several hundred of the species was examined (Dinan *et al*., 2001b, and unpublished data). It was also imperative to miniaturize the extraction and initial analysis procedure in order to maximize the throughput. Initial analysis was to be by bioassay (see below) and ecdysteroid-specific radioimmunoassay (RIA), both of which are very sensitive techniques. Therefore crushed seed samples, each weighing ca. 25 mg were extracted with methanol (3 × 1 ml, each for 3 h at 55 °C) and the pooled methanol extracts were diluted with water (1.3 ml) and partitioned against hexane (2 × 2 ml) to remove nonpolar lipids and pigments. The extraction procedure could thus be conveniently performed in Eppendorf vials and one could prepare extracts of 120 samples in 1.5 to 2 days. Initial analyses in two or three ecdysteroid-specific RIAs (DBL-1, Black and White antisera; all generous gifts from Prof. Jan Koolman, University of Marburg, Germany) and B_{II} bioassay (agonist and antagonist versions) of the neat, 10-fold, and 100-fold diluted extracts could reveal five classes of extract (Dinan *et al*., 1999c):

- negative in RIA and bioassay (ca. 90% of seed extracts); not examined further
- positive in agonist bioassay and/or RIA (ca. 5% of seed extracts); phytoecdysteroid-containing
- positive in the agonist bioassay, but negative in the RIA (two detected); nonsteroidal agonist-containing
- antagonist bioassay positive (ca. 3% of extracts); ecdysteroid antagonist-containing.
- A proportion of the neat extracts (5-10%) were cytotoxic and these were tested at greater dilution to determine if the cytoxicity was masking agonistic or antagonistic activities.

Aliquots of significantly positive antagonistic extracts were separated on reversed-phase C_{18} solid-phase extraction (SPE) cartridges to provide preliminary information about polarity of the active compounds. For several extracts, activity disappeared after SPE separation, so activity was probably a consequence of the synergistic activity of compounds of different polarities. Such extracts have not yet been examined further. Agonist/phytoecdysteroid-positive and strong antagonist extracts were separated on a standardized wide-polarity reversed-phase gradient system (25 cm × 4.6 mm i.d. Spherisorb ODS-2 column, 5 µm particle size, eluted at 1 ml min^{-1} with a linear gradient from 30% methanol/water to 100% methanol over 30 min, followed by 10 min at 100% methanol; monitored at 242 nm), which had been characterized by the determination of the retention times of a large number of phytoecdysteroid reference compounds (Dinan, 1995a). Fractions of 1 min duration were collected and analyzed by RIA and/or bioassay as appropriate. This served three major purposes: (1) it revealed how complex the biological activity profile in the sample was, (2) it provided initial information on the polarity of the active principles, and (3) it served as a dereplication procedure, so that the same compounds were not repeatedly extracted from different sources. All this information could be obtained from the initial extract of 25 mg seeds. If the initial analyses indicated the presence of novel or potent compounds, a larger batch of seeds (10–20 g) was extracted in order to isolate the compounds of interest.

A second strand to the strategy has been the assessment of isolated natural products to determine if they possess ecdysteroid agonist or antagonist activities. Many thousands of plant natural products have been isolated and identified, but most have not been assessed for any form of biological activity. Through the generosity of other researchers in providing samples, purchase and our own isolations, we have been able to assess several hundred pure compounds for agonist and antagonist activities in the B_{II} bioassay. These compounds represent members of the following classes of compounds: alkaloids, brassinosteroids, bufadienolides, cardenolides, cucurbitacins, diterpenes, ecdysteroids, flavonoids, lignans, limonoids, phenylalkanoids,

saponins, sesquiterpenes, vertebrate steroids, with asteroids (Dinan *et al.*, 2001a).

3.4.5.2. B_{II} Bioassay

Central to the success of the above strategy was the development of the B_{II} bioassay. Previous bioassays (review: Dinan, 1989), while effective, were too cumbersome and time-consuming for the rapid screening of many hundreds of samples. The *D. melanogaster* B_{II} cell line derived from hemocytes of a tumorous blood cell mutant (*l[2]mbn*) is ecdysteroid-responsive (Gateff *et al.*, 1980). Hemocytes contribute to the remodeling of larval tissues during metamorphosis by degrading those tissues which do not survive to adulthood. In the *l(2)mbn* mutant, the hemocytes are no longer able to recognize which tissues should remain undegraded. In the cell line derived from this mutant, the addition of ecdysteroids acts as a signal to induce phagocytosis and the cells develop from a uniform layer of small cells to form clumps of larger cells, surrounded by clear areas. This response lends itself to turbidometric quantification. It could be rapidly established that the B_{II} cells would grow readily in 96-well microtiter plates and that the bioassay, in principle, could work. However, validating the bioassay in terms of the crucial aspects of specificity, sensitivity, and robustness took much longer (Clément and Dinan, 1991; Clément *et al.*, 1993). It has been already shown that the B_{II} cells do not metabolize E, 20E, or PoA (Dinan, 1985). Extracts or purified compounds are assessed for their agonist activity by determining, if they can induce the characteristic ecdysteroid-specific response (cell clumping). Antagonistic activity is revealed by the ability to inhibit the clumping induced by 20E (5×10^{-8} M). Extracts/compounds/chromatography fractions are added to the wells of the microtiter plate and the solvent allowed to evaporate under sterile conditions. B_{II} cells (200 μl of 5×10^5 cells ml^{-1} in Schneider's medium containing 10% heat-inactivated fetal calf serum) are added to the wells. The microtiter plates are covered and stored in a humid environment at 25 °C for 7 days. The response is then quantified by reading the plate in a microplate reader (at 405 nm) and the response verified by examining the cells *in situ* with an inverted microscope. The latter differentiates between antagonistic and cytotoxic responses. This bioassay has the potential to be automated. The sensitivity of the assay is 0.5 ng 20E equivalents per well with a maximal response at 5×10^{-7} M 20E equivalents (50 ng per well). The inter- and intra-assay variation is <5% (Dinan *et al.*, 2001d). Consequently, it is possible to use the bioassay to quantify the relative potencies of active compounds, leading to the application of the bioassay to quantitative SAR (QSAR) (Dinan *et al.*, 1999c; Ravi *et al.*, 2001; Hormann *et al.*, 2003; Dinan, 2003). The EC_{50} for 20E is 7.5×10^{-9} M.

3.4.6. Agonists

3.4.6.1. Zooecdysteroids

The structures of the zooecdysteroids identified since 1985 can be accessed from http://www.ecdybase.org, together with information on sources, physicochemical properties, and citations for the first descriptions. Most novel ecdysteroids in recent years have been identified from noninsect invertebrates. The number of new zooecdysteroids identified in the last two decades (42) is rather few, reflecting the lower emphasis placed on steroid biochemistry in the last decades and the greater focus on molecular biology. The structural diversity of known zooecdysteroids (present in arthropods, other invertebrates or as metabolites of exogenous ecdysteroids in vertebrates) can be summarized as follows (based on a cholestane skeleton):

- hydroxyl groups at 2β, 3α, 3β, 5α, 5β, 6α, 11α, 14α, 16β, 20*R*, 22*R*, 23α, 25, 26/27
- keto groups at C3, C6
- unsaturation: $\Delta^{7(8)}$, $\Delta^{4(5)}$, $\Delta^{14(15)}$, $\Delta^{22(23)}$
- methyl: 24α, 24β
- ethyl: 24β
- side chain cleavage: C20/C22, C17/C20
- sequential oxidation of hydroxyl to aldehyde and carboxyl: C26
- acetoxy: 2β, 3β, 22
- long-chain fatty acid ester: C22
- glycolic acid ester: C22
- 4-hydroxybutanoic acid ester: C25
- phosphoryl: 2β, 3β, 3α, 22, 26
- sulphate ester: 26
- glucosyl: 22, 25
- glycolyl: C22
- A/B junction: *cis*, *trans*.

3.4.6.2. Phytoecdysteroids

Significantly more new phytoecdysteroids have been identified since 1985 than zooecdysteroids (http://www.ecdybase.org). The website provides chemical, spectroscopic, chromatographic, and biological information about every known ecdysteroid analog. Approximately 250 phytoecdysteroids are currently known. Researchers identifying new analogs are encouraged to submit their data to the website for inclusion. Recent advances in biological aspects of phytoecdysteroids have been reviewed

(Dinan, 2001) and are also covered elsewhere in this volume (see **Chapter 3.3**). The structural diversity of phytoecdysteroids can be summarized as follows:

- hydroxyl groups: 1α, 1β, 2α, 2β, 2α, 3β, 3α, 5β, 6α, 9α, 11α, 11β, 12β, 14α, 16β, 17α, 17β, C19, 20*R*, C21, 22*R*, 23α, 23ξ, 24α, 24β, 25, 26/27, C28, C29
- keto groups: C2, C3, C6, C7, C12, C17, C20, C22
- epoxy groups: 22α/23β
- unsaturation: $\Delta^{7(8)}$, $\Delta^{4(5)}$, $\Delta^{5(6)}$, $\Delta^{8(9)}$, $\Delta^{9(11)}$, $\Delta^{14(15)}$, $\Delta^{20(21)}$, $\Delta^{22(23)}$, $\Delta^{24(25)}$, $\Delta^{24(28)}$, $\Delta^{25(26/27)}$
- methyl: 4α, 23α, 24α, 24β
- ethyl: 23ξ, 24β
- side chain cleavage: C20/C22, C17/C20
- lactone rings: C24/C20 five-membered, C26/C22 six-membered, C26/C28 five-membered, C26/C29 six-membered, C29/C25 five-membered
- carboxylic acid methyl ester: C26
- side chain ether: C25/C22, C26/C22
- acetoxy: 2β, 3α, 3β, 20, 22, 25
- benzoyl: 2β, 3β, 20, 22, 25
- benzylidene acetal: C20/C22
- cinnamoyl: 2β
- coumaroyl: 3β
- crotonic acid ester: 3β
- 3-hydroxybutanoic acid ester: 22
- methoxy: 25
- phosphoryl: 3β
- pyrrole 2-carboxylic acid ester: 24ξ
- sulfuryl: 22
- glycosyl (glucosyl, galactosyl, xylosyl): 2β, 3β, 22, 24, 25
- acetonide: C2/C3, C20/C22
- A/B-junction: *cis*, *trans*.

3.4.6.3. Biological Activities of Ecdysteroids

The published data for the biological activities of ecdysteroids in a variety of arthropod bioassay systems have been reviewed recently (Dinan, 2003) and are included in Ecdybase. The most extensive set of biological activity data for ecdysteroids has been determined with the B_{II} bioassay. This data set (**Table 1**) is unique in its scope, the verification of the purity of the compounds and that it derives from a homogeneous assay. Less extensive data sets are available for the *in vitro* Kc cell bioassay (Cherbas *et al.*, 1980) and the *in vivo Calliphora*, *Musca*, and *Chilo* bioassays (review: Dinan, 2003).

In addition to naturally occurring ecdysteroids, the range of analogs for biological testing can be extended by chemical synthesis. This approach can be used to generate natural compounds that are not readily available (e.g., Suksamrarn *et al.*, 1994; Roussel *et al.*, 1995; Suksamrarn and Yingyongnarongkul, 1997) or for the preparation of analogs that are not present in nature, but which would be informative in generating SAR models (e.g., Harmatha and Dinan, 1997; Harmatha *et al.*, 2002) or in testing their predictions (e.g., Suksamrarn *et al.*, 2002; Dinan *et al.*, 2003). Conclusions deriving from SAR and molecular modeling studies are discussed below (see Section 3.4.9). The most active ecdysteroids discovered to date are PoA ($EC_{50} = 3.1 \times 10^{-10}$ M in the B_{II} bioassay), canescensterone ($EC_{50} = 5.3 \times 10^{-10}$ M in the B_{II} bioassay) (Dinan, 2003), 26-iodoponasterone A (9.0×10^{-10} M in the Kc cell assay) (Lee *et al.*, 1991) and 14-deoxymuristerone A (1.8×10^{-10} M in the Kc cell assay) (Cherbas *et al.*, 1980). Essentially all ecdysteroids show some biological activity in the B_{II} bioassay, with activities ranging over six orders of magnitude.

3.4.6.4. Brassinosteroids

Owing to certain structural similarities between the brassinosteroids and ecdysteroids, it was suggested that each group may demonstrate the biological activities of the other group. Both groups of steroids are polyhydroxylated and retain the full sterol side chain. However, the location and orientation of the hydroxyl groups (2α,3α- and 22,23-diols in brassinosteroids and 2β,3β- and 20*R*,22*R*-diols in ecdysteroids) and the configuration at C5 (5α-H in brassinosteroids and 5β-H in ecdysteroids) differ between the two steroid groups. Both groups possess a keto group at C6, but in ecdysteroids this is part of the characteristic 14α-hydroxy-7-en-6-one chromophore, while in brassinosteroids it may be part of a lactone.

The ability of seven brassinosteroids to induce the evagination of imaginal discs of *Phormia terranovae* has been assessed. Two of them (homodolicholide and castasterone) were able weakly to induce evagination at 10^{-4} M, while all the seven were able to inhibit the evagination induced by 20E. Castasterone and 22*S*,23*S*-homobrassinolide (**Figure 5**) were the most effective, but even here 5×10^{-5} M brassinosteroid was required to antagonize 5×10^{-7} M 20E fully (Hetru *et al.*, 1986). Lehmann *et al.* (1988) demonstrated that 22*S*,23*S*-homocastasterone and 22*S*,23*S*-homobrassinolide could compete with specifically bound [^{3}H]PoA associated with an ecdysteroid receptor preparation from *Calliphora vicina*. The K_d value for homocastasterone was calculated to be 5×10^{-6} M, with that of homobrassinolide being about 10-fold higher. These two brassinosteroids also retard molting in last instar nymphs of *Periplaneta americana* (Richter *et al.*, 1987), but demonstrate an ecdysteroid-like neurotropic activity

Table 1 Agonistic potencies of ecdysteroids in the *Drosophila melanogaster* B_{II} cell assay. Where compounds show no activity at 10^{-4} M, they are described as ''inactive''. Where the solubility is lower than 10^{-4} M, the activity is given as >[maximal solubility]

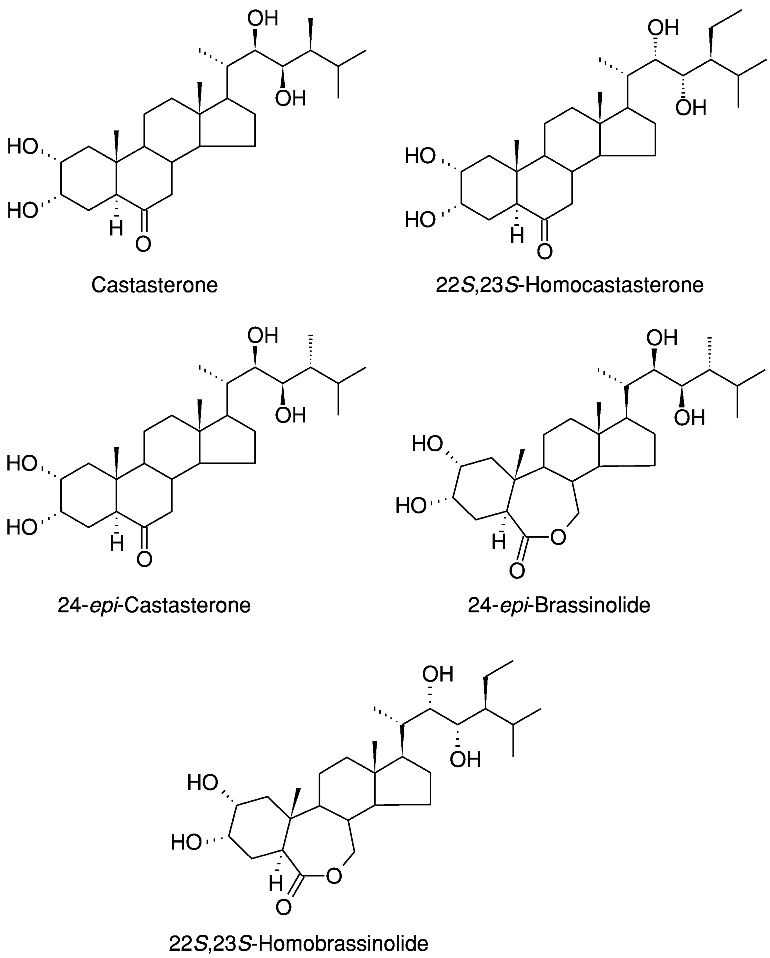

Figure 5 The structures of brassinosteroids showing ecdysteroid (ant)agonist activity.

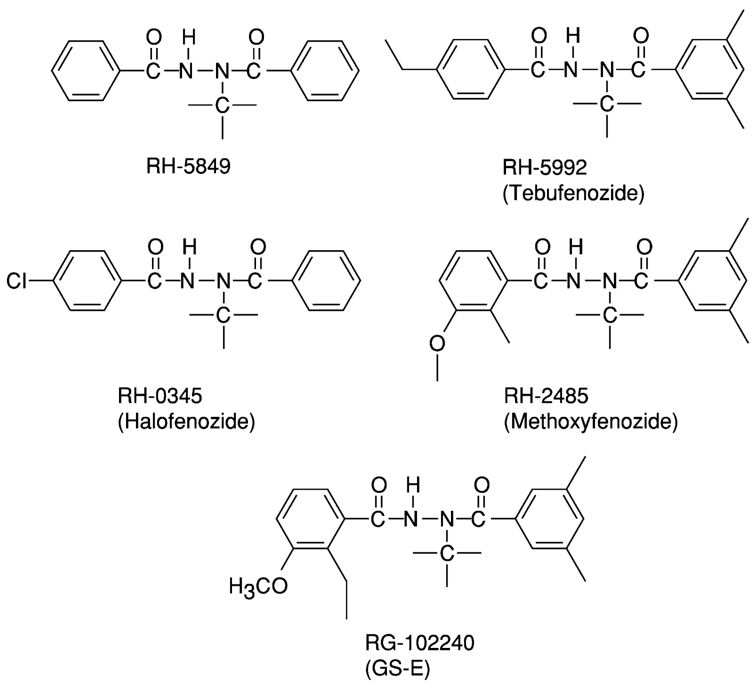
in the same species (Richter and Adam, 1991). Spindler *et al.* (1992) examined the effects of 22*S*,23*S*-homobrassinolide and 22*S*,23*S*-homocastasterone on an ecdysteroid-responsive *Chironomus tentans* cell line and found that both were weak agonists in terms of their ability to induce ecdysteroid-specific responses and that both competed weakly for specifically-bound [^{3}H]PoA in cell-free

extracts of the *C. tentans* cells. Assessment of 10 brassinosteroids in the *D. melanogaster* B_{II} bioassay revealed no agonist or antagonist activity even at their limit of solubility (10^{-4} or 10^{-3} M) (Dinan *et al*., 2001d). In *Spodoptera littoralis*, 24-epibrassinolide and 24-epicastasterone can compete specifically-bound [^{3}H]PoA with K_d values of 3.7 and 2.0 μM, respectively (Smagghe *et al*., 2002). However, these compounds did not induce evagination of *S. littoralis* imaginal discs even at 100 μM or when fed to last instar larvae. In view of the low concentrations of brassinosteroids in plants, any ecdysteroid (ant)agonist activity they may possess will not be biologically relevant. However, given the chemical similarities between brassinosteroids and ecdysteroids, it is of interest to determine which structural modifications are required to convert molecules of one class to others with the biological activity of the other class. Hybrid brassinosteroid/ecdysteroid molecules have been generated and tested in the B_{II} bioassay (for ecdysteroid agonist/antagonist activity) and in the rice lamina inclination test (for brassinosteroid-like activity) (Voigt *et al*., 2001).

3.4.6.5. Diacylhydrazines

Owing to the chemical and physical properties of ecdysteroids, it is not possible to regard them as potential insecticidal compounds in their own right (Dinan, 1989). Prospects lie in the identification of nonsteroidal analogs which retain biological activity, but are chemically simpler and more resistant to metabolic and/or environmental degradation. The first nonsteroidal ecdysteroid agonists were identified at Rohm & Haas Co. in the late 1980s (Wing, 1988; Wing *et al*., 1988). The prototypical molecule was RH-5849 (**Figure 6**), which was shown to bind to ecdysteroid receptors with relatively low affinity, but, because it is metabolized only slowly, it is able to induce premature molting and death in treated insects. As a result of the synthesis and assessment of a very large number of diacylhydrazines (DAHs), Rohm & Haas could identify and develop analogs as commercially viable insecticides, starting with RH-5992 (tebufenozide) and followed by RH-0345 (halofenozide) and RH-2485 (methoxyfenozide). These compounds possess very low mammalian toxicities and even show some selectivity for certain orders of insects. The DAHs are treated more extensively elsewhere in this series (see **Chapter 6.3**), and the focus here will be on SARs for DAHs (see Section 3.4.9). There is considerable interest in modeling possible overlaps between DAH and ecdysteroid binding to the ligand-binding domain of the EcR (see below). Although many (165) DAHs have been assessed in the B_{II} bioassay (**Table 2**), none has yet been identified which possesses antagonistic activity.



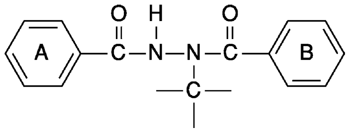


Figure 6 Structures of prototypical and commercially relevant diacylhydrazines.

3.4.6.6. 8-*O*-Acetylharpagide

The iridoid glucoside 8-*O*-acetylharpagide (Figure 7), isolated from *Ajuga reptans* (Labiatae), was reported to possess weak ecdysteroid agonist activity (Elbrecht *et al*., 1996). Unfortunately, *A. reptans* is also a rich source of phytoecdysteroids and it is now clear that 8-O-acetylharpagide, *per se*, possesses no agonistic activity and that the activity is attributable to contaminating ecdysteroids (Dinan *et al*., 2001c).

3.4.6.7. DTBHIB

The synthetic compound 3,5-di-*tert*-butyl-4-hydroxy-*N*-isobutylbenzamide (DTBHIB) (Figure 7) is reported to be a weak ecdysteroid agonist, as it induces ecdysteroid-specific changes in the *D. melanogaster* Kc cell line ($EC_{50} = 3 \times 10^{-6}$ M) and is able to displace [^{3}H]PoA from receptors *in vitro* ($EC_{50} = 6 \times 10^{-6}$ M). However, the isopropyl analog showed no activity in either test (Mikitani, 1996).

3.4.6.8. Maocrystal E

As part of an extensive survey of natural products to detect those showing ecdysteroid agonist or antagonist activities in the B_{II} bioassay (Dinan *et al*., 2001a), it was found that the diterpene maocrystal E (isolated from *Isodon* spp. (Labiatae)) (Li *et al*., 1985) showed agonist activity ($EC_{50} = 5 \times 10^{-6}$ M). Further, maocrystal E (Figure 7) competed with [^{3}H]PoA for the ligand binding site of *D. melanogaster* and *Choristoneura fumiferana* EcR complexes (EcR/USP) with K_i values of 8.6×10^{-6} M and 5.8×10^{-5} M, respectively. These data support the interaction of maocrystal E with the ligand-binding domain.

3.4.6.9. Tetrahydroquinolines

Researchers at FMC Corp. (Princeton, NJ, USA) have indicated that 4-phenylamino-1,2,3,4-tetrahydroquinolines also act as ecdysteroid agonists (Dixson *et al*., 2000). More recently, RheoGene investigators have pursued this chemistry in the context of EcR gene switch actuation (Smith *et al*., 2003) (see Section 3.4.9.4).

3.4.7. Antagonists

3.4.7.1. Ecdysteroids

Although many ecdysteroids have been identified (Lafont *et al*., 2002) (see **Chapter 3.3**), relatively few had until recently been assessed for their biological activity, let alone to determine whether they possess agonistic or antagonistic activity. Apart from ajugalactone (see Section 3.4.3.3), there are no literature reports concerning antagonistic ecdysteroids. Approximately 150 ecdysteroid analogs have now been assessed in the B_{II} bioassay and very recently one of these was shown to possess antagonistic activity. 24ξ-Hydroxydihydrocarthamosterone (Figure 8) had been isolated as a minor

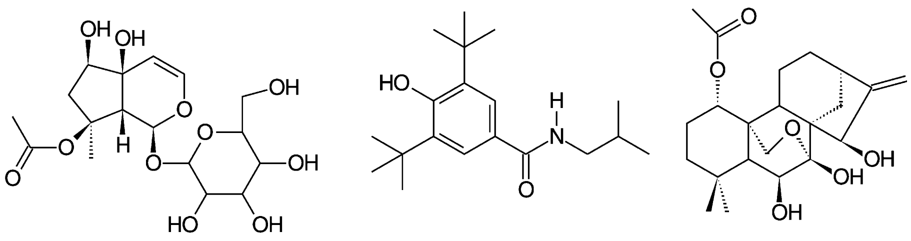

Figure 7 The structures of 8-*O*-acetylharpagide, 3,5,-di-*tert*-butyl-4-hydroxy-*N*-isobutylbenzamide (DTBHIB), and maocrystal E.

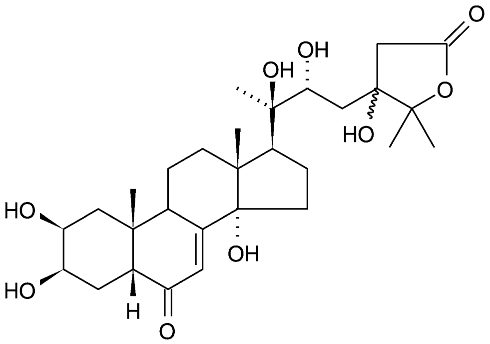

Figure 8 The structure of 24ξ-hydroxydihydrocarthamosterone.

ecdysteroid from *Leuzea carthamoides* (Compositae) and has an EC_{50} value of 2.0×10^{-5} M versus 5×10^{-8} M 20E. To verify that the compound is antagonistic, it has been shown that the biological activity co-chromatographs with the ultraviolet (UV)-absorbing peak on high-performance liquid chromatography (HPLC) (Harmatha and Dinan, unpublished data). The stereochemistry of the antagonistic ecdysteroid has not yet been fully elucidated, but it will be interesting to determine what makes this compound antagonistic, while other closely related compounds (e.g., carthamosterone) are agonistic.

3.4.7.2. Brassinosteroids

See Section 3.4.6.4 above.

3.4.7.3. Withanolides

The first evidence that certain withanolides can act as ecdysteroid antagonists was obtained in 1996, when a series of 16 withanolides isolated from *Iochroma gesnerioides* (syn. *I. coccineum*: Solanaceae; Alfonso *et al.*, 1991, 1993; Alfonso and Kapetanidis, 1994) were assessed in the B_{II} bioassay (Dinan *et al.*, 1996). None of the compounds showed agonist activity, but several exhibited distinct antagonist activity. The activities of four of these were adequate for quantification to determine EC_{50} values (versus 5.0×10^{-8} M 20E): 2,3-dihydro-3β-methoxywithaferin A ($EC_{50} = 3.5 \times 10^{-5}$ M), 2,3-dihydro-3β-methoxywithacnistine (1.0×10^{-5} M), 2,3-dihydro-3β-methoxyiochromolide (5.0×10^{-6} M), and 2,3-dihydro-3β-hydroxywithacnistine (2.5×10^{-6} M) (see **Figure 9** for corresponding structures) (note that the configuration of the C3 oxygen-containing substituent was determined as 3β after the publication of the paper; Sarker, Šik and Dinan, unpublished data). The active compounds possessed an α,β-unsaturated lactone in the side chain, a 3β-oxygen-containing function and a 5β,6β-epoxide.

A further 23 purified withasteroids have been assessed for their ecdysteroid agonist/antagonist activities (Dinan *et al.*, 1997a, 2001a). None of these demonstrated antagonistic activity, but one of them, withaperuvin D, was active as an agonist ($EC_{50} = 2.5 \times 10^{-5}$ M). This compound also possesses an α,β-unsaturated lactone in the side chain, but the side chain is linked 17α to the ring system. It also possesses a 3α,6α-epoxide with 5β-H, which is unusual amongst withasteroids. Further SAR studies are required to elucidate the structural features required for antagonism and antagonism.

3.4.7.4. Cucurbitacins

Amongst the first 200 plant extracts to be assessed with the B_{II} bioassay for the presence of ecdysteroid (ant)agonists, the methanolic extract of *Iberis umbellata* (Cruciferae) demonstrated distinct antagonist activity. A literature search revealed that cucurbitacins are characteristic of certain members of this genus (Gmelin, 1963). Bioassay-guided HPLC fractionation of the seed extract gave two UV-absorbing peaks which corresponded to the biological activity. Subsequent identification by nuclear magnetic resonance (NMR) and mass spectrometry revealed them to be cucurbitacin B and cucurbitacin D (**Figure 10**) (Dinan *et al.*, 1997b).

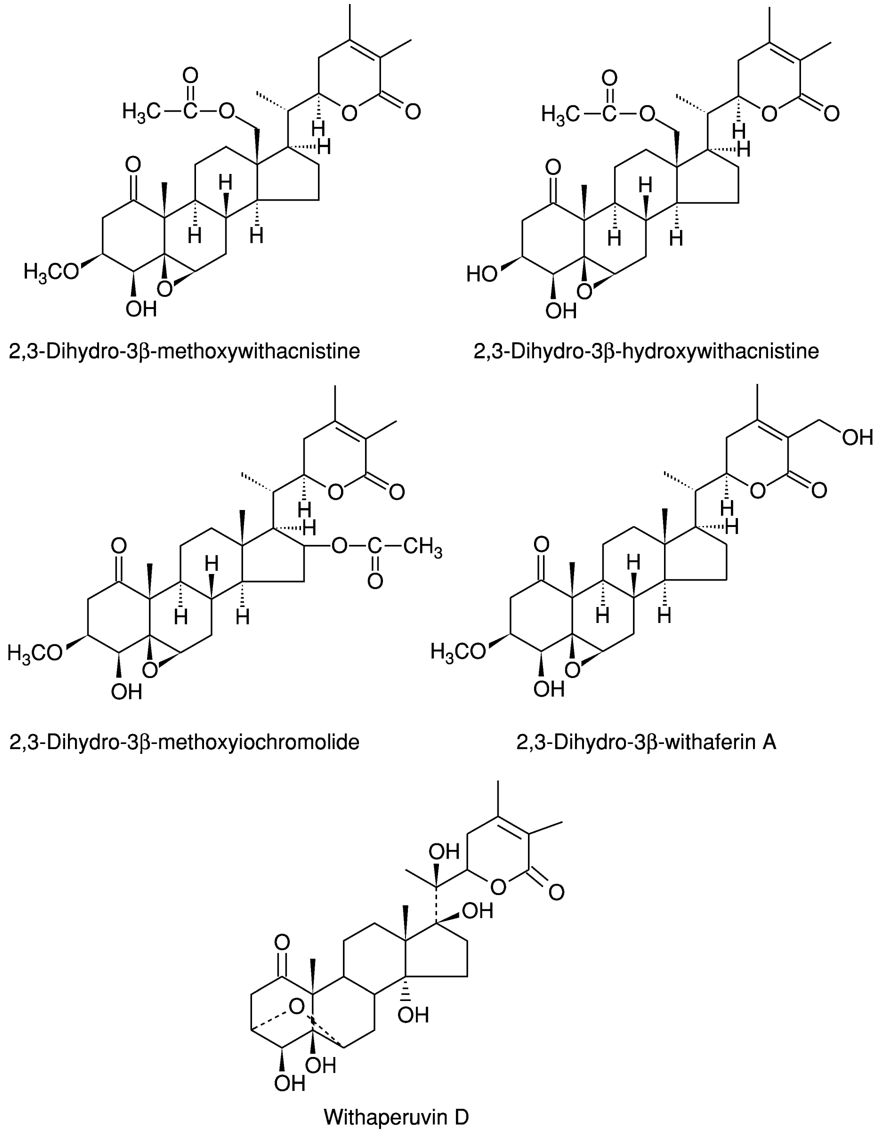

Figure 9 Structures of withasteroids active as ecdysteroid (ant)agonists.

The purified compounds antagonize the action of 20E (5×10^{-8} M) in the B_{II} cells; cucB ($EC_{50} = 1.5 \times 10^{-6}$ M) and cucD ($EC_{50} = 1.0 \times 10^{-5}$ M). Both compounds also compete with [^{3}H]PoA for the ligand binding site of EcR complexes extracted from B_{II} cells, the K_d for cucB being 5.0×10^{-6} M. CucB also antagonizes the 20E-induced stimulation of a transfected ecdysteroid-regulated reporter gene in *D. melanogaster* S2 cells and prevents the formation of 20E-induced complex formation of EcR/USP/EcRE complexes as examined by gel-shift assays. Preliminary SAR studies suggest that the Δ^{23}-22-oxo functional grouping is responsible for the antagonistic activity. In fact, hexanorcucurbitacin D, which lacks this functional grouping, is a weak agonist and 5-methylhex-3-en-2-one, which mimics C22 to C27 of the side chain of cucurbitacin D, is also a weak antagonist. Thus, cucurbitacins B and D are unequivocal EcR antagonists.

Subsequent studies with cucurbitane-type compounds isolated from *Hemsleya carnosiflora* (Cucurbitaceae) revealed that several of these antagonize 20E action in the B_{II} bioassay (Dinan *et al.*, 1997c). The active principles of further antagonistic plant extracts have been shown to result from the presence of cucurbitacins, e.g., cucurbitacin D from *Cercidiphyllum japonicum* (Cercidiphyllaceae) (Sarker *et al.*, 1997b) and cucurbitacin D, cucurbitacin F, and 3-*epi*-cucurbitacin D from *Physocarpus opulifolius* (Rosaceae) (Sarker *et al.*, 1999b).

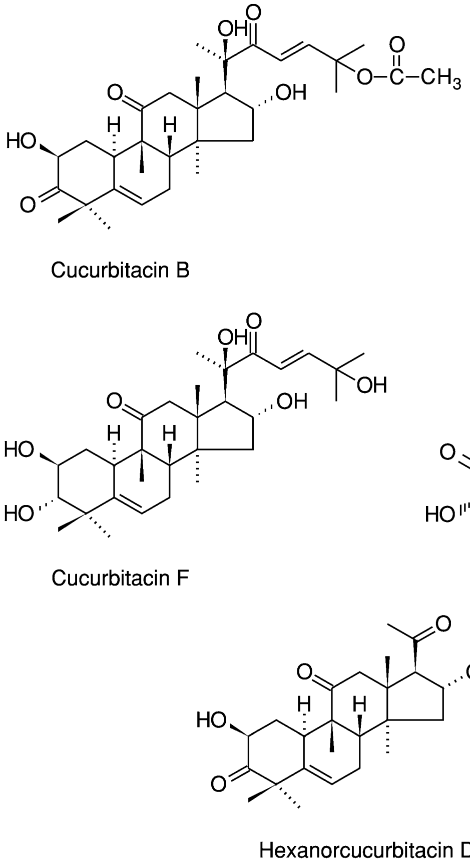

Figure 10 Structures of cucurbitacins active as ecdysteroid (ant)agonists.

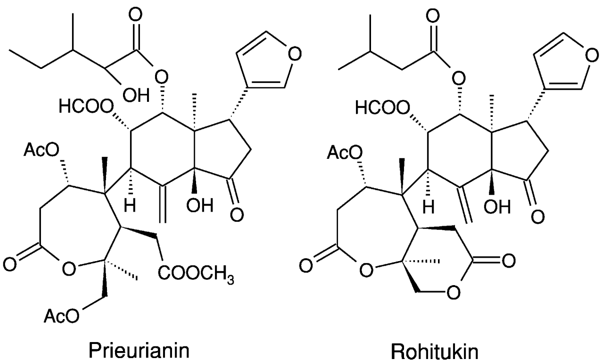

Figure 11 Structures of limonoids active as ecdysteroid antagonists.

3.4.7.5. Limonoids

The methanolic extract of seeds of *Turraea obtusifolia* (Meliaceae) showed antagonistic activity. Bioassay-guided purification resulted in the identification of two limonoids, prieurianin and rohitukin (**Figure 11**) (Sarker *et al.*, 1997a). Neither compound was particularly active (EC_{50} values $= 10^{-5}$ M and 1.3×10^{-4} M, respectively, versus 5×10^{-8} M 20E). Several other purified limonoids have been assessed for activity (Dinan *et al.*, 2001a), but only nomilin and obacunanone were found to have weak antagonistic activity. Azadirachtin, which had been suggested to act as an ecdysteroid antagonist, was also inactive (Lehmann *et al.*, 1988; Clément *et al.*, 1993). It has not yet been determined whether the active limonoids interact with the ligand binding domain of the EcR, somewhere else on the receptor complex or at some other point in the transduction pathway. In view of the wide diversity of natural limonoid structures and their general effects on

insect feeding, growth, and development (Isman, 1995), a wider range of limonoids should be assessed in the B_{II} bioassay and in a range of ecdysteroid-responsive systems from other insect species to determine the real significance of this class of ecdysteroid antagonist.

3.4.7.6. Stilbenoids

Methanol extracts of seeds of several species of *Paeonia* (Paeoniaceae) proved to be antagonistic. The antagonistic activity of one of these (*P. suffruticosa*) was examined more closely and the activity was found to be associated with *cis*-resveratrol and three oligostilbenes, named as suffruticosols A, B, and C (Sarker *et al.*, 1999a). Further, antagonistic stilbenoids have been isolated from *Iris clarkei* (Iridaceae) (Keckeis *et al.*, 2000) and *Carex pendula* (Cyperaceae) (Meng *et al.*, 2001a). The structures of the isolated stilbenoids are presented in **Figure 12**, while the biological activities are summarized in **Table 3**. The remarkable observation arising from consideration of the relationship between activity and structure is that the various stilbenoids possess similar activities, even though they differ enormously in molecular size from monostilbenes like *cis*-resveratrol through di-, tri-, and tetrastilbenes. The stilbenoids from *C. pendula* (kobophenol B, *cis*-miyabenol A, and *cis*-miyabenol C) compete with [^{3}H]PoA for the ligand binding site on the EcR complex (Meng *et al.*, 2001a). It is difficult to envisage how molecules of such differing sizes can interact with the ligand binding domain, although the planar nature of the molecules may facilitate this.

3.4.7.7. Phenylalkanoids

Purified phenylalkanoids (**Figure 13**) were assessed for ecdysteroid agonist and antagonist activity because they have a wide range of bioactivities, including insecticidal activity (Perrett and Whitfield, 1995). Six phenylalkanoids have been assessed (Dinan *et al.*, 2001a) and all were found to possess antagonistic activity, of which marginatine ($EC_{50} = 5.0 \times 10^{-5}$ M versus 5×10^{-8} M 20E) was found to be the most active.

3.4.7.8. Industrial Compounds

Endocrine disruption is currently an area of considerable, and increasing, concern. Most research to date has been conducted on aquatic vertebrates (fish and mammals) and the emphasis has been placed on disruption involving members of the nuclear receptor superfamily. As EcRs are also members of this superfamily and aquatic arthropods fill important ecological niches and are of great significance in food webs, endocrine disruption in invertebrates could have even more impact, affecting several trophic levels. Research in this area is hampered by restricted knowledge of invertebrate endocrinology (especially with regard to aquatic species) and the vast number of man-made and natural compounds released into the environment, which might potentially act as endocrine-disrupting chemicals (EDCs) (DeFur *et al.*, 1999). The simplicity and robustness of the B_{II} bioassay lend themselves to its use as a preliminary screen to identify potential EDCs, since many compounds can be rapidly tested to determine if they act as ecdysteroid agonists or antagonists. The few active compounds can then be taken forward for more extensive (and very time-consuming) *in vivo* testing using appropriate invertebrate species. *In vivo* studies alone very rarely give conclusive information on the mode of action of toxic chemicals, complicating the identification of EDCs by this approach, while a cell-based receptor assay does not reflect the full complications (penetration, metabolism, sequestration, excretion, receptor cross-talk, etc.) of a biological organism. Consequently, the two approaches are complementary and an approach using the B_{II} bioassay as a pre-screen to identify the potentially developmentally disruptive chemicals allows one to proceed to *in vivo* testing on a rational basis. Several hundred environmental chemicals have now been tested for ecdysteroid (ant)agonist activity in the B_{II} bioassay (Dinan *et al.*, 2001d; Cary *et al.*, unpublished data). Several weak antagonists have been identified, of which diethylphthalate (DEP), bisphenol A (BPA), and lindane (**Figure 14**) are the most signficant, both in terms of their potencies and the amounts released into the environment (Dinan *et al.*, 2001d). For each of these three compounds we could demonstrate that the antagonistic activity co-chromatographs with the named compound (i.e., is not associated with an impurity) and that the compound competes with [^{3}H]PoA for the ligand binding domain of the EcR complex. However, the EC_{50} values (2.0×10^{-3} M, 1.0×10^{-4} M, and 3.0×10^{-5} M for DEP, BPA, and lindane, respectively; versus 5×10^{-8} M 20E) are high and, given the concentrations of these compounds in the environment, it is unlikely that they are true invertebrate EDCs, although the caveats about the differences between *in vitro* and *in vivo* assessments mentioned above and the possibility that other species could be more susceptible than *D. melanogaster* should be borne in mind. Others are also beginning to use *in vitro* assays for the identification of potential invertebrate EDCs (Oberdörster *et al.*, 1999, 2001).

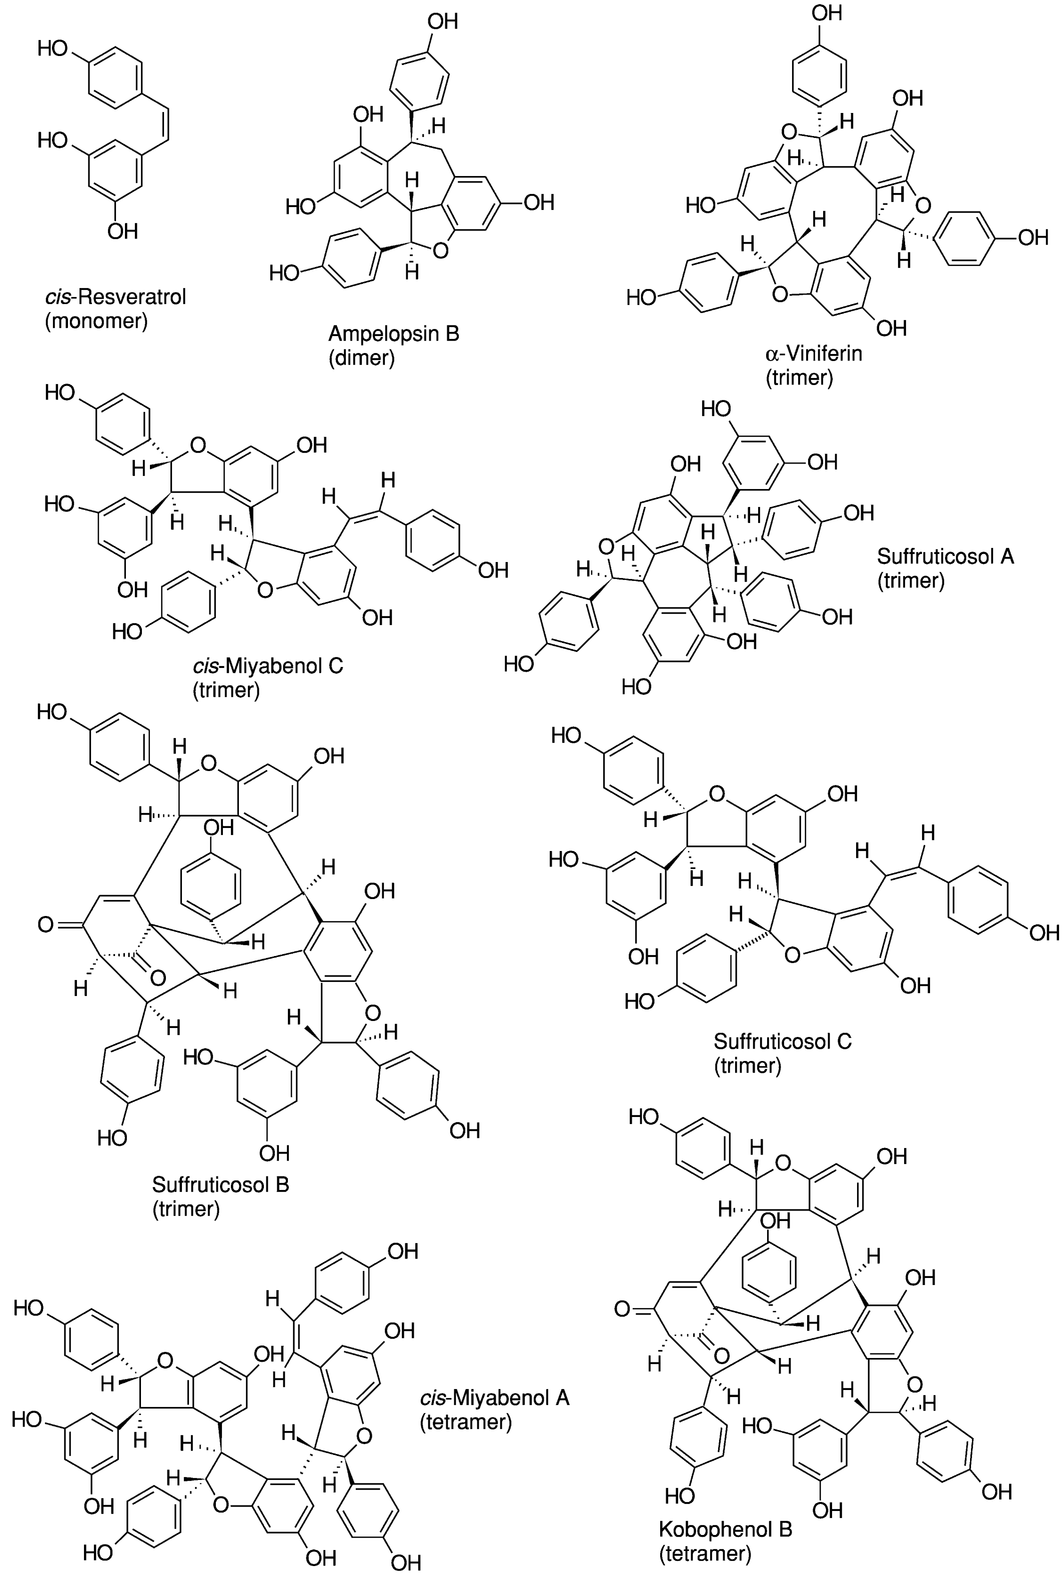

Figure 12 Structures of stilbenoids active as ecdysteroid antagonists.

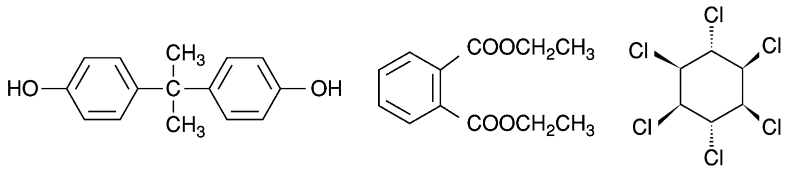
3.4.8. Functions of Natural Ecdysteroid (Ant)Agonists in Insect–Plant Relationships



3.4.8.1. Agonists

When phytoecdysteroids were first discovered, it was suggested that they were a defense against insect predators (Galbraith and Horn, 1966). However, it soon became clear that certain insect species are highly resistant to ingested ecdysteroids (review: Dinan, 1998). It is now generally accepted that phytoecdysteroids contribute to deterrence of nonadapted phytophagous invertebrate predators, either by acting as antifeedants (mediated by taste receptors) or as hormonal toxicants on ingestion. Some 5–6% of terrestrial plant species accumulate phytoecdysteroids (Imai *et al.*, 1969), of which approximately half contain the compounds at levels which in themselves would deter nonadapted insect predators (Dinan, 1995a). Ecdysteroids may still contribute to the protection of plant species containing lower levels, since the ecdysteroids may interact synergistically with other secondary compounds. There appears to be a relationship between the occurrence and levels of phytoecdysteroids in the food plants of a particular insect species and its ability to cope with ecdysteroid in its diet (Blackford and Dinan, 1997). Thus, monophagous species such as larvae of the peacock butterfly (*Inachis io*) which feeds on ecdysteroid-negative stinging nettle (*Urtica dioica*; Urticaceae) would rather starve to death than consume nettle leaves coated with even low levels of 20E, while larvae of the oligophagous cinnabar moth (*Tyria jacobeae*) which encounter some ecdysteroid-containing plants in its host-range are moderately resistant to ingested ecdysteroids, but suffer developmental defects on the ingestion of larger amounts.

No studies have been yet performed on the role of maocrystal E in insect–plant interactions.

3.4.8.2. Antagonists

It has been realized for some time that compounds such as cucurbitacins, withanolides, stilbenoids, phenylalkanoids, and limonoids contribute to plants' protection strategies against invertebrate predators (Ascher *et al.*, 1980; Govindachari *et al.*, 1995; Miró, 1995; Perrett and Whitfield, 1995), but little was known about the mechanism(s) of action. The characterization of members of these classes of compounds as EcR antagonists has provided a testable hypothesis for the investigation of their roles in insect–plant relationships. All the active compounds identified so far have relatively weak affinities for the *D. melanogaster* EcR complex (K_d values in the μM range). This may reflect the low cost to the plant in producing these compounds and the high energy cost to phytophagous insects of detoxifying large amounts of such compounds (Dinan *et al.*, 2001b).

Bisphenol A Diethylphthalate Lindane

Figure 14 Structures of potential environmental disruptors interacting with ecdysteroid receptors.

3.4.9. QSAR and Molecular Modeling

3.4.9.1. Ecdysteroid SAR and QSAR

The early literature on ecdysteroid SAR studies has been reviewed (Bergamasco and Horn, 1980; Horn and Bergamasco, 1985; Dinan, 1989). The various bioassays employed vary in their complexity of performance and interpretation. A number of factors can affect the potency of a test compound to a greater or lesser extent depending on the assay system: penetration, metabolism, excretion rate, sequestration, and target site activity. *In vivo* assays will give a measure of all of these acting in concert, but not allow the individual contributions to be identified. On the other hand, cell-free receptor assays probably give a much more direct measure of target activity, but may bear little resemblance to the *in vivo* situation.

Horn and Bergamasco (1985) summarized their main conclusions regarding ecdysteroid SAR in insect systems as follows:

- an A/B *cis*-ring junction is essential
- a 6-oxo-7-ene grouping is essential
- a full sterol side chain is essential
- a free 14α-hydroxyl group is essential
- 2β-, 3β-, and 20*R*-hydroxyl groups enhance biological activity
- a C25 hydroxyl diminishes activity.

These conclusions were empirically derived from data combined from a number of different bioassay systems (mainly the *Calliphora*, *Musca*, and *Sarcophaga* assays, the *Chilo* dipping test and the *D. melanogaster* Kc cell assay). On the basis of the above summary, Bergamasco and Horn (1980) visualized the ecdysteroid interacting with the ligand binding pocket of the receptor at three major sites: the β-face of the A- and B-rings, the α-face in the region of the 14α-hydroxyl group, and the side chain from C22 to C27. Later, uniform data from the B_{II} bioassay enabled quantification of the potency contributions to the B_{II} EC_{50} by individual structural features, by making direct pairwise comparisons between structures which differ only in a single feature (**Table 4**) (Dinan *et al.*, 1999c).

Table 4 Ecdysteroid structural modifications and contributions to B_{II} $p(EC_{50})$

Potency-enhancing modifications	*Δp(EC50)*	*Potency-diminishing modifications*	*Δp(EC50)*
+2β-OH	2.28	3β-OH → 3-=O	−0.74
+20-OH	1.35	β-C-3 → α-C-3	−0.0
+14α-OH	0.60	+5β-OH	−0.25
+22*R*-OH	0.47	*trans* → *cis* C/D-junction	−1.44
22-OH → 22-=O	0.04	6-=O → 6-OH (α or β)	−1.89
		+11β-OH	−1.87
		20*R*-C- → 20*S*-C	−1.72
		22*R*-OH → 22*S*-OH	−0.60
		+22-OH, +25-OH	−0.34
		+24-CH_3 (*R* or *S*)	−0.85
		+25-OH	−0.89
		25-OH → 24/25 C=C	−0.91

In this way the previous SAR could be qualitatively substantiated and enhanced. Significantly, the previous SAR formulation described primarily as a brief collection of essential molecular features could now be cast in terms of the cumulative contribution, both enhancing or diminishing, of an expanded feature set (**Table 4**). In the language of pharmacophore analysis, the most highly contributing features are hydrogen bond donors or acceptors attached to C2, C3, C6, C20, and C22 together with a lipophilic group extending from C22. These groups are arranged approximately according to the geometry shown in **Figure 15**, wherein the ring sizes and ring junction stereochemistry determine the exact distances and angles. No single functional group is essential for ecdysteroidal potency; noteworthy is that the 14α-OH group can be replaced with unsaturation or can be altogether removed without abolishing B_{II} bioassay activity. Available data conflict as to a uniformly positive contribution of the 14α-OH to the pharmacophore.

More recent work involving examination of selected ecdysteroid probe sets in engineered EcR mammalian gene switch assays or in Sf-9 cells

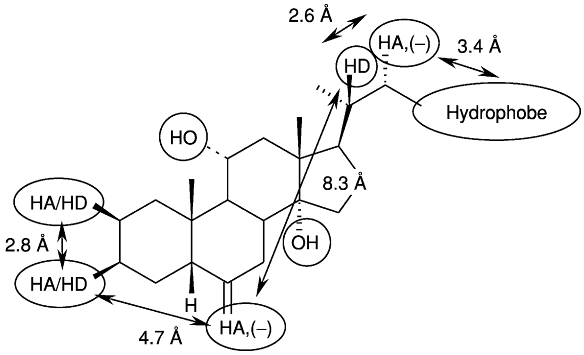


Figure 15 Ecdysteroid pharmacophore. Features are generalized where possible; HA, hydrogen bond acceptor; HD, hydrogen bond donor; (−), polar negative atom.

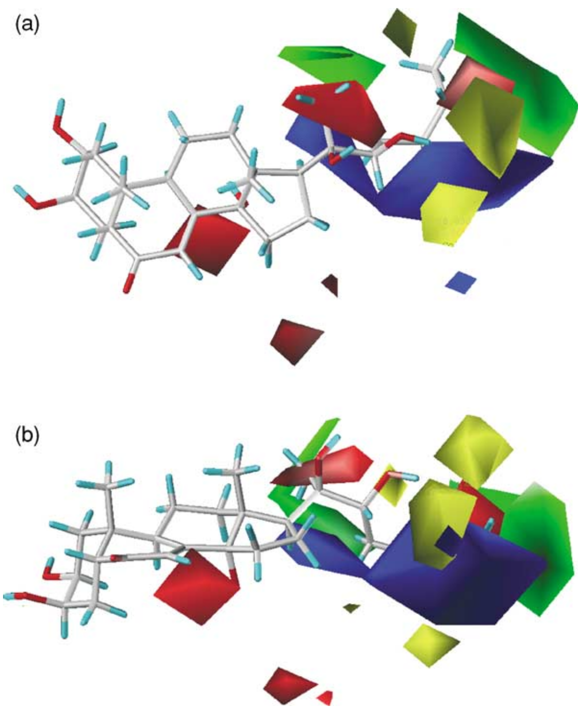

Figure 16 Comparative molecular field analysis (CoMFA) electrostatic field contour plot (standard deviation × coefficient) for favored ecdysteroid CoMFA model. Blue/red polyhedra represent regions where positive charge is favored/disfavored; contribution level = 85/8%, respectively. Green/yellow polyhedra represent sterically favored/disfavored regions; contribution level = 80/25%, respectively. Ponasterone A (PoA) is depicted. (a) View from the β-face; (b) view towards the C6/C14 edge of the steroid. Sci. 41*, 1587–1604; © American Chemical Society.)

is roughly consistent with the previous SAR (Nakagawa *et al.*, 2000a; Saez *et al.*, 2000). The available ecdysteroid datasets are unfortunately too limited for quantitative analysis by classical QSAR. However, quantitative analysis was performed on the B_{II} data set using the multidimensional comparative molecular field analysis (CoMFA) approach (Dinan *et al.*, 1999c; Ravi *et al.*, 2001). By the CoMFA method, the intensity of steric and electrostatic fields at specified points in a three-dimensional lattice is measured and tallied as a function of each member ecdysteroid of the QSAR training set. Thereby, a descriptor table of many columns is generated. Partial least-squares supplies the appropriate statistical treatment to manipulate the data and derive a QSAR expression. This expression is best depicted as color-coded surfaces or polyhedra describing regions in space where the presence of generalized pharmacophoric features would be expected to either enhance or diminish efficacy.

For the ecdysteroids, a CoMFA model was developed with an $r^2 = 0.92$ and a cross-validated r^2 (q^2) of 0.593 for a 67-member training set and an average residual of fit of 1.47 p(EC_{50}) units for a 16-member test set (**Figure 16**). The model is characterized by a large (+)-charge-enhancing region (blue) wrapped around the steroid side chain and (+)-charge-diminishing regions (red) at O20, between C26 and C27, and below C7/C8. Steric-enhancing regions (green) appear distal to C21 and at the terminus of the side chain. Steric-diminishing regions (yellow) appear around the perimeter of the side chain. The CoMFA is consistent with, and extends, the simple functional group-oriented pharmacophore of **Figure 15**, and provides an abstraction useful for evaluating new or hypothetical structures which might not fit into the simple functional group schema.

The four-dimensional QSAR (4D-QSAR) method (Hopfinger *et al.*, 1997) provides another complementary view of ecdysteroid QSAR in the B_{II} assay. In 4D-QSAR, structures for analysis are passed through a molecular dynamics simulation, and the QSAR descriptors are derived from the frequency that particular atom types might populate individual cells in a three-dimensional lattice enveloping the training set structures. Thus, in contrast to CoMFA, 4D-QSAR takes conformation into account. The method can help discriminate among ligand alignment postulates and can provide optimal ligand conformation hypotheses. Data reduction is accomplished by partial least-squares, and models are selected and optimized by use of a genetic algorithm.

4D-QSAR was applied to essentially the same training set as used for the CoMFA modeling, resulting in four complementary models ($r^2 = 0.83$–0.88, $q^2 = 0.76$–0.80), one of which is depicted in **Figure 17** (Ravi *et al.*, 2001). Taken together, the 4D-QSAR

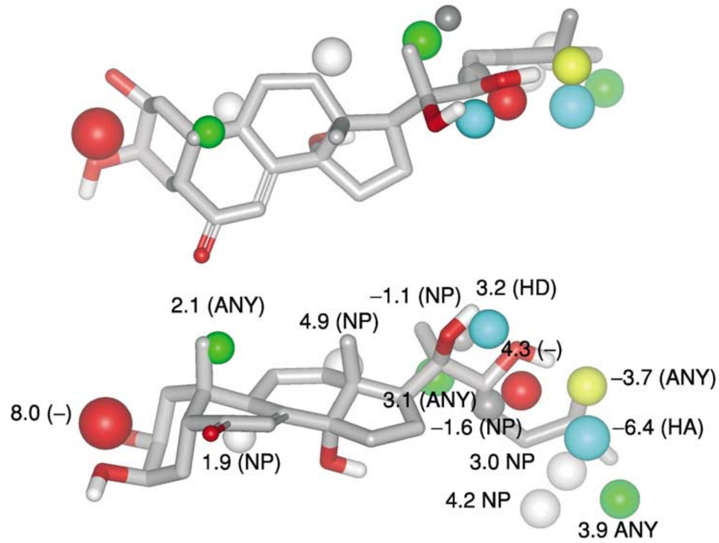

Figure 17 One of the favored ecdysteroid four-dimensional quantitative structure–activity relationship (4D-QSAR) models relative to PoA in its postulated active conformation. Alignment is based on atoms 6, 12, and 16. No external whole molecule descriptors were used in this model. The grid cell occupancy descriptors (GCODs) are shown as spheres. Interactive pharmacore element (IPE) type abbreviations: ANY, any atom (green/yellow); NP, nonpolar (white/gray); (−), polar negative (red/blue); HD, hydrogen bond donor (cyan/pink); HA, hydrogen bond acceptor (pink/cyan). Positive values of a GCOD indicate that occupancy by the appropriate IPE increases activity while a negative value indicates occupancy decreases activity. (Reproduced with modification and permission from Ravi M., Hopfinger A.J., Hormann R.E., Dinan L., **2001**. 4D-QSAR analysis of a set of ecdysteroids and a comparison to CoMFA modeling. *J. Chem. Inform. Comput. Sci. 41*, 1587–1604. © American Chemical Society.)

models corroborate the CoMFA conclusions, and also specify structural requirements more precisely. The 4D-QSAR models indicate that the hydroxyl group at C2 should be a hydrogen bond acceptor, the hydroxyl at C20 should be a hydrogen bond donor, the atom attached to C22 should be polar and bear a partial negative charge (and is a likely hydrogen-bond acceptor, although HA/HD role swapping with O20 is possible), and that there should be no hydrogen bond acceptor at C25. The general picture generated by the ecdysteroid CoMFA and 4D-QSAR models is that in the ligand binding cavity of the EcR, the steroid side chain lies in a sterically restrictive hydrophobic cylinder with hydrogen-bonding functionality near O20 and O22. Interestingly, analysis of weakly active ecdysteroids in the 4D-QSAR models indicates that the potency depression is often due not so much to an offending functional group as it is to the inability to assume a non-offending conformation.

Homology modeling of the EcR ligand-binding domain and ecdysteroid docking generated several interesting hypotheses for ecdysteroid–EcR binding, notwithstanding serious challenges owing to the absence of homologous nuclear receptors with identity any greater than ca. 30%, and, of course, the absence of a publicly available EcR crystal structure itself (see **Chapter 3.5**). Wurtz *et al.* (2000) have proposed two models for ecdysteroid interaction with the dipteran *C. tentans* EcR ligand binding domain, based on homology models built from the ligand binding domains of the human retinoic acid receptor (hsRARγ) and the human vitamin D receptor (hsVDR). Both models insert the steroid side chain in a "tail-first" orientation, such that ring-A remains closest to the enclosing Helix-12. Between these two models, the orientation of 20E differs by roughly 180°, thereby altering the interactions between the functional groups on 20E and the residues lining the ligand binding pocket. Another model built at Rohm & Haas, based on estrogen receptor (ER), thyroid harmone receptor (TR), and vitamin D receptor (VDR) and docked with 20E in the "tail-first" orientation, was successfully used to guide mutant generation for selective modulation of ecdysteroid responsiveness, while leaving DAH sensitivity unaltered (Kumar *et al.*, 2002). A more recent model has been constructed by investigators at Sankyo and Nippon Kayaku (Kasuya *et al.*, 2003).

The CoMFA and 4D-QSAR view of a hydrophobic cylinder surrounding the side chain, the hydrogen bond acceptor characteristics of 22OH, and the hydrogen bond donor characteristic of 20OH can all be easily reconciled with the CtEcR (*C. tetans*) 20E-liganded homology models based on either the retinoic acid receptor (RAR) or the VDR, as well

as with the generally hydrophobic ligand binding domain characteristics of known nuclear-receptor ligand binding domains on which these models are based (Wurtz *et al*., 2000). On the other hand, the CtEcR homology models predict that all six hydroxyls and the C6 carbonyl of 20E are implicated in H-bonding, whereas the receptor-independent 4D-QSAR and CoMFA models do not recognize 14OH in any significant way, and strongly suggest that 25OH is not involved in hydrogen bonding. *A fortiori*, simple empirical SAR of the 25 position indicates that 25OH is detrimental to EcR affinity. Despite these conflicts, the bulk of empirical SAR, multidimensional QSAR analysis, homology modeling, and docking generally provide a consistent picture of the factors involved in ecdysteroid activity.

While it is significant and reassuring that the calculational models and qualitative SAR are generally in concordance with each other and with ecdysteroid binding data and physiological data, a more stringent test is in consonance with a crystal structure of EcR bound with an ecdysteroid. The ligand-binding domains of EcR/USP from *Heliothis virescens* (HvEcR) co-crystallized with PoA at ~3 Å resolution considerably enlightens our understanding of ecdysteroid SAR (Billas *et al*., 2003). In this structure, PoA assumes a pose similar to vitamin D in VDR, in which the steroid assumes a crescent shape with its side-chain proximal to Helix-12 ("head-first"), and the A-ring is held in a chair conformation. Hydoxyl groups at carbons 2 (R383), 3 (E309), 14 (T343/T346), and 20 (Y408) as well as the C-6 carbonyl (A398) all participate in hydrogen-bonding. Moreover, the interacting residues are generally conserved across insect species, which concurs with the ubiquity of PoA recognition. The HvEcR residues near the side-chain terminus are generally hydrophobic, consistent with qualitative SAR and QSAR models, which all discount 25-OH as a pharmacophore element. The combined CoMFA and 4D-QSAR models correctly interpreted/predicted the crescent shape, A-ring chair conformation, hydrophobic quality, and steric permissiveness of the distal portion of the side-chain, and the identity of most hydrogen-bonding units (**Figure 15**). However, whereas 4D-QSAR models predicted that C-22 would be involved in hydrogen bonding as an acceptor, the HvEcR crystal structure indicates no such role. Likewise, although qualitative SAR and QSAR models lead one to the conclusion that the C-14 hydroxyl may not necessarily be advantageous for binding, the HvEcR crystal structure clearly shows not one, but two hydrogen-bonding interactions at this position.

In interpreting the immensely valuable EcR crystal structures, one should keep in mind that dynamics exert a significant role in ligand–protein interactions, and that multiple ligand-binding modes may be possible. For example, some of the homology modeling that antedates the HvEcR–PoA crystal structure hypothesizes a "tail-first" ecdysteroid orientation – a hypothesis testable through careful docking studies and possibly multiple crystal structures. Although hydrogen-bonding HvEcR residues are generally conserved across species, nonconserved binding pocket residues may provide a means for supplementary or substitute binding interactions, particularly if the specific ecdysteroid analog in question offers complementary features for such hypothetical alternative interactions.

3.4.9.2. Diacylhydrazine SAR and QSAR

3.4.9.2.1. Lepidopterans The diacylhydrazines (**Figure 18**) have enjoyed the most extensive qualitative and quantitative analysis, owing to commercial interest and the relative abundance of analogs. The chemotype was first synthesized and identified as an insecticide in the early 1980s (Hsu and Aller, 1991), and shortly thereafter reported as an ecdysteriod agonist (Wing, 1988; Wing *et al*., 1988). Using Kc cells, competitive binding studies indicated that RH-5849 (1,2-dibenzoyl-1-*tert*-butylhydrazine) is a competitive inhibitor with PoA with a K_d value of 2 μM, which implies that the two ligands share a common binding domain. Depression of the PoA kinetic on-rate, but not the off-rate, by RH-5849 are consistent with affinity for a common steroid/DAH binding site rather than an allosteric site. DAH toxicity to caterpillars is attributable to hyperecdysteroidism and premature initiation of molting. For an initial set of 28 DAHs, Kc cellular response is proportional to propensity toward head capsule apolysis in the tobacco hornworm, *Manduca sexta* (Wing *et al*., 1988). Hsu (1991) described an initial

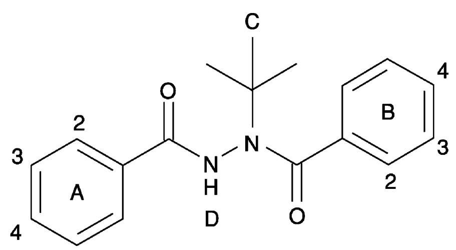

Figure 18 Diacylhydrazine (DAH) notation and numbering system.

DAH SAR for toxicity toward southern armyworm (*Spodoptera eridania*) as follows:

1. A- and B-regions: when A or B is phenyl and C is *tert*-butyl, toxicity is retained when the alternate A or B group is an aryl, aromatic heterocycle, aliphatic cycle or short alkenyl. Acyclic alkyl or benzyl are somewhat less active.
2. C-region: a bulky group is essential, but excessive size significantly truncates potency. *Tert*-butyl confers the optimum blend of foliar and plant systemic potency. Some functionality, such as cyano, is permissible.

Later, Rohm & Haas investigators updated the empirical SAR for southern armyworm toxicity (Hsu *et al.*, 1997):

1. A- and B-region: aryl > heterocyclic; asymmetric A/B-substitution > symmetric A/B-substitution.
2. A-region (monosubstituted, B = phenyl): 2-Cl, 2-CH_3, 3-Cl, 3-OCH_3, 4-Et, 4-Br, 4-I, 4-CH_3, 4-CF_3, 4-OCH_3, > H > 2-Br, 2-NO_2, 2-CF_3, 2-NH_2, 2-OCH_3, 3-CH_3, 3-Et, 3-NO_2, 4-Cl, 4-iPr, 4-*t*-Bu.
3. B-region (monosubstituted, A = phenyl): 2-ethyl, 2-I, 2-Br, 2-NO_2, 2-Cl, 3-Br, 3-ethyl, 3-methyl, 3-Cl, 4-Cl, 4-F > H > 2-OCH_3, 2-CH_3, 2-NH_2, 3-CF_3, 3-OCH_3, 3-NO_2, 3-NH_2, 4-NO_2, 4-CH_3, 4-OCH_3.
4. D-region: H or hydrolyzable group.
5. Backbone: C = O > C = S, S = O; NH–N(tbu) > CH_2–N(tbu), NH–CH(tbu).

Significantly, nonlinear, intra-ring, and interring substituent relationships were observed, thereby presenting a challenge for lead optimization which nonetheless proceeded steadily to the invention of RH-5992 (tebufenozide), and later advanced to the development of RH-2485 (methoxyfenozide), insecticides.

More recent reports from Sankyo and Nippon Kayaku Co. describe qualitative DAH SAR pertaining to structures related to chromafenozide insecticide (Sawada *et al.*, 2003a, 2003b, 2003c). Various DAHs with heterocycles fused to the 3,4-positions of the A-ring are toxic toward the common cutworm (*Spodoptera litura*). The most active compounds have oxygen and carbon-containing, five- or six-membered fused rings devoid of bulky or hydrogen bond-donating substitution. Optimized structures also bear a small substituent at the A2 position, typically methyl (a pattern shared with methoxyfenozide), while the remainder of the molecule reflects the structure of RH-5992. With respect to the C-module, considerable potency is retained when neopentyl, 1-*t*-butyl-ethyl, or 1,1-dimethylbenzyl replace the *t*-butyl group. Hence, once the A- and B-modules are optimized, the C-module becomes less refractory towards structural modulation. Many of these observations are implicit in earlier DAH patent literature; however, patent data format generally does not lend itself to SAR analysis. Additional D-module SAR from Sankyo and Nippon Kayaku (Sawada *et al.*, 2003c) and the observation that dibenzoyl cyclic hydrazides are inactive (Toya *et al.*, 2002) remain consistent with the earlier hypothesis that only hydrolyzable or readily metabolizable groups are tolerated in the D-module, and that the bioactive chemical species at the EcR is a DAH with a free amide NH. Notwithstanding, the observation that alkoxycarbonylmethyl groups are tolerated as the D-module does challenge the earlier, more restrictive hypotheses concerning the amide NH (Cao *et al.*, 2001).

The DAH chemotype is well suited for Hansch–Fujita QSAR (Hansch and Leo, 1995), and a number of QSAR relationships have been proposed by Nakagawa and colleagues to describe aspects of DAH insect toxicity under varying circumstances. The Hansch approach considers combinations of substituent physiochemical properties and other simple molecular properties as descriptors of the biological activity. The result is a multiple linear regression equation, which, if demonstrated to be robust statistically, can be quite instructive in its quantitative description of the structural factors responsible for potency.

In examination of DAH toxicity to larvae of *C. suppressalis* for a series of 46 DAHs unsubstituted on the A-ring and monosubstitued on the B-ring, it was determined that the level of toxicity is positively influenced by elevated log *P* and elevated electronic inductive effect (σ_I) of the *ortho*-substituent (Oikawa *et al.*, 1994a). Potency is suppressed by voluminous *meta*- and *para*-substituents as well as multiple (2, *n*) substitution patterns. The same training set with *Chilo* data was later examined by simply measuring the distance from the A-carbonyl oxygen to the attachment atom of the B-subsitutent for DAHs represented in a crystal structure-like conformation (Qian, 1996). A parabolic relationship was found with an optimal distance of ca. 4.6 Å. An almost identical training set was used to determine the SAR for toxicity toward larvae of the beet armyworm (*Spodoptera exigua*); this turned out to be highly correlated with toxicity toward *Chilo* larvae, and could be described by a very similar regression equation ($n = 41$; $s = 0.275$; $r^2 = 0.959$; descriptors: log *P*, σ_I, $V_{ortho, meta, para}$, indicator variables for mutliply substituted members). For a complementary training set in which the B-ring was held constant with a near-optimized 2-Cl substituent and

the A-ring pattern was varied, the following equation for *Chilo* toxicity was derived:

$$\mathrm{pLD}_{50} = (0.722)\Delta\log P - (0.74)\Sigma\Delta L_{ortho} - (0.868)\Sigma\Delta V_{\mathrm{w}}^{meta} - (0.485)\Delta L_{para} + 6.653$$
$$n = 44,\ s = 0.284,\ r = 0.896,\ F_{4,39} = 39.5 \qquad [1]$$

This equation states that for the training set with A-ring variation, toxicity to *Chilo* larvae is positively influenced by high $\log P$ and negatively influenced by the length of substituents in the *ortho*- and *para*-positions and the summed volume of the *meta*-substitutents (Oikawa *et al.*, 1994b). Thus, the most active DAHs in this series bear small lipophilic substituents which increase the $\log P$, and therefore pLD_{50}, to a greater degree than their size detracts from activity. When a very similar training set was tested against beet armyworm larvae, an exactly analogous regression equation was developed ($n=42$, $s=0.273$, $r^2=0.902$, descriptors: $\log P, \Delta L_{ortho}, V_{\mathrm{w}}^{meta}, L_{para}$) reflecting toxicity highly correlated with that of *Chilo* (Smagghe *et al.*, 1999).

Several related QSAR studies were perfomed with *Chilo* in which the ecdysteroid-agonist response was measured not by toxicity, but rather by the rates of chitin synthesis in cultured integument fragments from diapause larvae (Nakagawa *et al.*, 1995b, 2000a). The first study on 37 B-2-Cl and A-unsubstituted DAHs, members of the training sets from the two prior studies on *Chilo* larvae, also resulted in a linear regression with terms resembling the sum of terms from the two prior *Chilo* studies ($n=37$, $s=0.288$, $r^2=0.872$, $F_{9,27}= 20.43$). The second study used a training set consisting of 23 DAHs heavily represented by structures in which one or the other aryl ring was replaced by a saturated ring or chain. Here, a QSAR was developed which described integument activity in terms of a positive influence by $\log P$ and a negative influence by the distances between the carbonyl carbons and the distal carbon atoms on the same side of the hydrazine linkage. In a Hansch study using larval toxicity of the spruce budworm, a set of 10 A- or B-ring monosubstituted DAHs showed a positive correlation of toxicity to substituent π-lipophilicty values and a negative correlation to substituent length (L), more or less independent of substituent position (Mohammed-Ali *et al.*, 1995).

The classical QSAR approach is attractive for its simplicity. It can provide straightforward insights for ligand design. The method is limited, however, by application to datasets with a common core region, and classical QSAR's potential for underparameterization can easily lead to oversimplification (Hansch and Fujita, 1995). Addressing these issues in the context of DAH QSAR, the three-dimensional CoMFA approach has been applied to a balanced set of 37 A- and B-ring substituted DAHs aligned in the crystal structure conformation, and using ecdysteroidal-responsive *N*-acetylglucosamine incorporation of *Chilo* integument as the dependent variable. The steric field exerts the most dominant role in the model (52.5% contribution) with potency-diminishing contours located in A- and B-ring positions reassuringly consistent with the two *Chilo* Hansch analyses described above ($r^2=0.845$, $q^2=0.438$, $s=0.292$, four components). $\log P$ contributes to a level of 10.7%; the remainder of the descriptors arise from the electrostatic field (Nakagawa *et al.*, 1995a).

3.4.9.2.2. Nonlepidopterans The initial report of the ecdysteroidal properties of DAHs correlated the hyperecdysonistic response in larvae of a lepidopteran, *M. sexta* with the affinity for a dipteran, *D. melanogaster* EcR in Kc cells for an early set of DAHs (Wing, 1988; Wing *et al.*, 1988). This observation presaged research in defining the physiological and physiochemical reasons for the exquisite lepidopteran selectivity of DAHs. The general understanding which has emerged is that: (1) species susceptibility to DAH toxicity is primarily a function of the intrinsic affinity of the DAH to the specific EcR, (2) the general DAH chemotype has the greatest affinity for lepidopteran EcRs; DAH subsets have moderate affinity for coleopteran and dipteran EcRs, (3) ecdysteroid affinity is fairly consistent across insect species while DAH affinity modulates above or below 20E or PoA potency levels, depending upon species, (4) absorption, distribution, metabolism, excretion, and insect behavior may modulate, but do not usually significantly affect, the toxicity levels determined primarily by EcR affinity (Smagghe *et al.*, 2001). These general conclusions have been thoroughly reviewed (Hsu *et al.*, 1997; Dhadialla *et al.*, 1998; Carlson, 2000).

The isolation of the locus of biological activity and selectivity to the EcR enables the interpretation of QSARs in terms of receptor binding pocket interactions and facilitates direct quantitative comparisons across species. For the coleopteran Colorado potato beetle (*Leptinotarsa decemlineata*), fourth instar larvae were monitored for toxicity after topical application of a set of 45 A-ring unsubstitued DAHs (Nakagawa *et al.*, 2001b). Unlike a closely analogous DAH set examined in *C. suppressalis*, which showed a uniformly augmenting effect from $\log P$ and ($\sigma_{\mathrm{I}}^{ortho}$) and a negative influence by V_{w}^{meta} and multiple substitution, DAH toxicity in *L. decemlineata* exhibits a more complex convex

parabolic relationship to hydrophobicity, which can be expressed in terms of the π-value of substituents in the *meta*-position, and which is enhanced by large *ortho*-substitents ($V_w^{ortho}, \Delta B_1^{ortho}$). Only the diminishing effect of large *para*-substitents (*C. suppressalis*: V_w^{para}, *L. decemlineata*: ΔB_5^{para}) is analogous across these two species. Overall, there is no clear correlation of toxicity between these two species. Interestingly, the *ortho*-*sec*-butyl substituent was found to be quite favorable for activity against *L. decemlineata*. Examining the substituent effects on the A-ring while the B-ring is held constant as 2-Cl (another DAH set closely analogous to one described above for *C. suppressalis*) the following equations were developed to describe two distinct DAH subclasses (Nakagawa *et al.*, 1999):

$$\mathrm{pLD}_{50} = (0.887)\log P + (0.395)\Delta B_5^{ortho} + (0.435)E_s^{meta} + (0.65)E_s^{para} + (1.09)\mathrm{HB} + 2.97$$
$$n = 28, s = 0.328, r^2 = 0.842, F_{5,22} = 10.68 \quad [2]$$

$$\mathrm{pLD}_{50} = (-1.695)\log P - (0.527)\Sigma E_s^{ortho} - (0.766)\Sigma E_s^{meta} - (0.916)\Sigma E_s^{para} + 9.23$$
$$n = 16, s = 0.373, r^2 = 0.885, F_{4,11} = 9.982 \quad [3]$$

Here, the effect of hydrophobicity is expressed in two equations with a single log *P* term rather than a multiterm expression in one equation. One DAH subclass, which is more populous and tends to be monosubstituted, increases in toxicity with increasing log *P* (eqn [2]), while the second subclass, generally multisubstituted, shows the opposite effect (eqn [3]). As with *C. suppressalis* toxicity, in *L. decemlineata*, the first subclass exhibits a toxicity-intensifying effect from log *P*, but unlike *C. suppressalis*, a diminishing effect from sterically requiring substituents in all positions (cf. eqn [1]). For the second subclass, the situation is completely reversed with respect to log *P* and substituent sterics. To highlight the dichotomy of lepidopteran versus coleopteran SAR, the lepidopteran-optimized DAHs, tebufenozide and methoxyfenozide, were observed to be at least two orders of magnitude weaker than the coleopteran-optimized DAH, halofenozide, in *L. decemlineata* ($\mathrm{pLD}_{50} = 3.38$, 3.29 versus 6.09), while in the lepidopteran *S. exigua*, almost the opposite is the case ($\mathrm{pLD}_{50} = 7.5$, 8.18 versus 6.1; Smagghe *et al.*, 2003).

A direct comparison of *L. decemlineata* toxicity with that of *C. suppressalis* and *S. exigua* by the CoMFA method illuminates the disparate balance of structural factors responsible for toxicity in the larval stages of these organisms (Smagghe *et al.*, 2003). Earlier toxicity data from all three organisms for a common set of 59 DAHs exemplifying modifications on both rings was used to build CoMFA/CoMSIA (comparative molecular similarity indices analysis) models (Klebe, 1998) by a uniform procedure. All models retained a significant steric component. However, whereas the resultant *S. exigua* and *C. suppressalis* models greatly benefited from hydrophobic field and surface area contributions, as well as other factors, the favored *L. decemlineata* model was dominated by sterics with an additional contribution only from electrostatics (for all three models, $r^2 = 0.843$–0.958, $q^2 = 0.583$–0.683, 5–6 components). The models were optimized on test set r^2 (24–50 test set members) as well as training set q^2 in order to produce a QSAR tool which would be predictive as well as explanatory (adjusted test set $r^2 = 0.40$–0.465).

Another CoMFA analysis was performed on a balanced set of 100 DAHs modeled in the folded crystal structure conformation (Chan *et al.*, 1990) and tested in the *Drosophila* $\mathrm{B_{II}}$ assay (Dinan, 2003; Dinan and Hormann, unpublished data). Many of the training set members examined against *C. suppressalis* and *L. decemlineata* appear in the *Drosophila* model. Sterics, electrostatic, and hydrogen bond donor/acceptor fields all play a balanced role with log *P* in explaining ecdysonergic activity ($r^2 = 0.903$, $q^2 = 0.737$, five components). Not only do the field contributions differ from prior lepidopteran or coleopteran models, the *Drosophila* $\mathrm{B_{II}}$ field contours vary significantly as well (**Figures 19** and **20**).

In addition to the native inducible gene expression systems discussed so far, engineered heterologous systems may shed light not only on ligand–EcR recognition, but also on secondary factors which could modulate the specific EcR–ligand interaction. A set of 146 DAHs spanning considerable substituent space were analyzed in a gene switch derived from *Bombyx* EcR and utilizing endogenous RXR as partner protein and β-galactosidase as reporter in stably transfected human kidney cells (Suhr *et al.*, 1998; Hormann *et al.*, 2002). The ligands were modeled in the folded conformation. From these data, CoMFA/CoMSIA ($r^2 = 0.633$, $q^2 = 0.831$, five components) and 4D-QSAR models ($r^2 = 0.709$, $q^2 = 0.644$) were constructed and evaluated with a 30 member test set (average residual fit = 0.493–0.521 pEC_{50} units). The favored CoMFA models utilized hydrogen bonding fields and the CoMSIA hydrophobic field in addition to steric and electrostatics in rather complex contours. A large hydrophobic contour appears in the region between the two aromatic rings. The favored 4D-QSAR model is characterized by several aromatic grid cell occupancy descriptors in addition to the more common

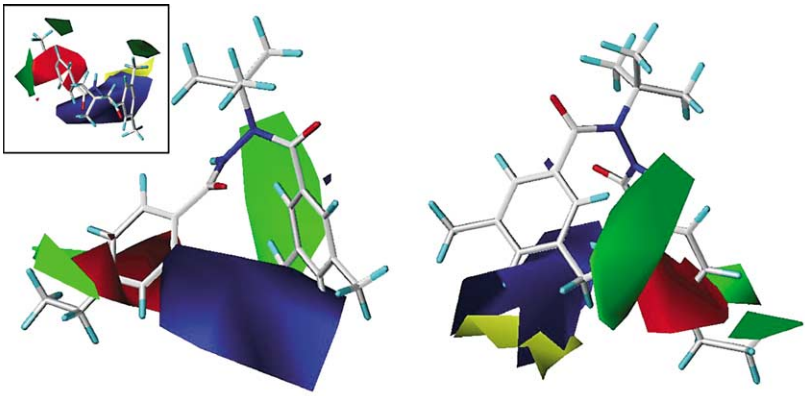

Figure 19 CoMFA electrostatic and steric field contour plot (standard deviation × coefficient) for DAH CoMFA model of B_{II} data. Blue/red polyhedra represent regions where positive charge is favored/disfavored; contribution level = 75/25%, respectively. Green/yellow polyhedra represent sterically favored/disfavored regions; contribution level = 65/35%, respectively. Tebufenozide is depicted.

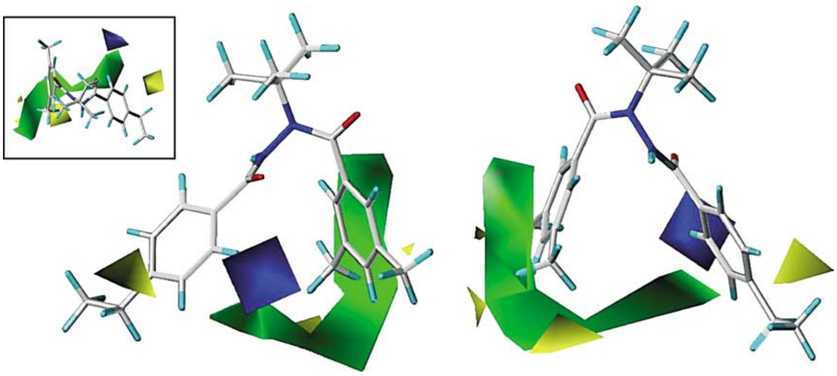

Figure 20 CoMFA hydrogen bond field contour plot (standard deviation × coefficient) for DAH CoMFA model of B_{II} data. Blue/red polyhedra represent regions where hydrogen bond donation is favored/disfavored; contribution level = 70/30%, respectively. Green/yellow polyhedra represent hydrogen bond acceptor favored/disfavored regions; contribution level = 70/30%, respectively. Tebufenozide is depicted.

any-atom and nonpolar atom type descriptors; most grid cell occupancy descriptors (GCODs) are clustered around the more distal regions of the aromatic rings. Model building with a number of trial alignment hypothesis strongly suggests that the DAHs align in the *Bombyx mori* EcR cavity principally according to one or more of the backbone atoms, in contradistinction to one or the other of the benzamide fragments.

3.4.9.2.3. Pharmacophores The pharmacophoric features common to all sensitive insect orders are:

1. Two hydrogen acceptor or polar negative atoms space approximately approximately 3.5–4.0 Å apart.
2. A bulky, conformationally-determining (see below) lipophilic group located asymmetrically between the two negative centers.
3. Moderately sized (about six carbons) groups on either side of the negative centers.
4. A hydrogen bond-donating group is highly advantageous when located near the alternate negative center.

The pharmacophore has been most aptly manifested in mono-*N*-substituted diacylhydrazides. Toxicity optimized for both lepidopterans and coleopterans favors aryl groups with substituent types which tend to be small and nonhydrogen bond donating (Figure 21). Lepidopteran activity is enhanced with A-ring substitution at the 4-position with 1–2 carbon lipophilic groups or, alternatively, with a 2,3- or a 2,[3,4]-ring substitution pattern. B-ring patterns are less specific, but substitution in the 2-, 2,5-, 3,5-, or 3,4,5-positions can be favorable. Coleopteran activity, on the other hand, is optimized only with the most parsimonious selection of one or

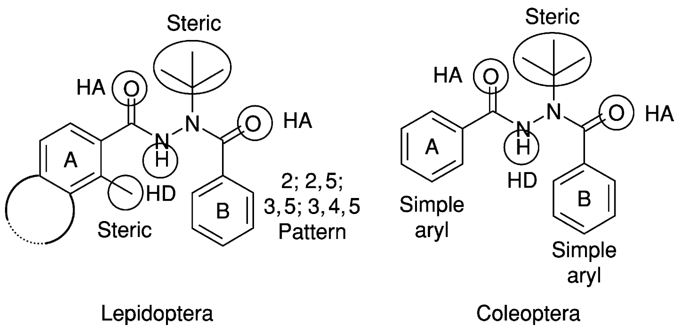

Figure 21 Diacylhydrazine pharmacophore for two insect orders.

two small groups, exemplified by halofenzozide having a single chlorine at the A4 position.

The known binding pose of the DAH chemotype in HvEcR (Billas *et al*., 2003) is a folded conformation with P-helicity (vida infra), wherein the *t*-butyl group points downward approximately toward the H6/7 loop and the A-ring is orientated towards the H7/10 interface. The A-ring *ortho*-methyl substituent of the studied ligand, BY-106830, is orientated to its exterior. Hydrogen-bonding interactions are made with the A-ring carbonyl (N504), B-ring carbonyl (T343), and NH group (Y408). The *t*-butyl group lies in a hydrophobic pocket comprising residues from H3, H11, the H6/7 loop and the H11/12 loop (Billas *et al*., 2003). Overall, this binding pose is quite unusual and considerably shifted in position relative to ligands of other nuclear receptors, which, when viewed together, maintain a fairly consistent center of mass more to be likened to PoA bound in HvEcR. EcR crystal structure-naive docking studies have generally placed DAHs in a more conventional position (Wurtz *et al*., 2000; Kumar *et al*., 2002). The DAHs are generally globular and do not exhibit completely dissymmetric and pronounced electrostatic surface markings. Thus, in homology model docking studies, DAH orientation tends to be multimodal. It remains to be seen what DAH docking to a genuine EcR structure will reveal.

The conclusions from qualitative SAR, QSAR studies, and Lepidopteran pharmacophore analysis depicted in **Figure 21** are consistent with the DAH–protein interactions implicated by the HvEcR/BY-106830 crystal structure. The authors attribute the Lepidopteran specifity of the DAH BY-106830 to the lepidopteran-conserved residue, V384, which is complementary in shape, hydrophobicity and particularly the size of the 3,5-dimethyl substitution of the BY-106830 B-ring. In other insect orders, methionine occurs at this residue position and is prohibitively sterically demanding (Billas *et al*., 2003). It will be very interesting to see in the future just how DAHs actually do bind to non-lepidopteran EcRs.

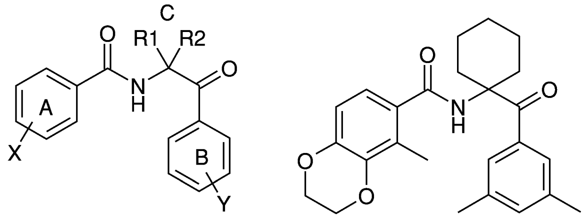

Figure 22 The amidoketone (AMK) generalized and lead structures.

3.4.9.3. Amidoketone SAR

The amidoketones (AMK) have been disclosed recently as an EcR-active chemotype (Tice *et al*., 2003a, 2003b). These compounds invoke an isosteric replacement of the B-*t*-butyl amide in the DAHs with a disubstituted ketone, thereby nullifying the long-held precept that nitrogens are required in the backbone. The AMKs are effective as gene switch inducers in systems based on BmEcR/RXR (*B. mori*) in HEK cells or on CfEcR/β-RXR-LmUSP (*C. fumiferana*, *L. migratoria*) in Chinese hamster ovary cells. AMK SARs for these two receptors indicate a pattern reflecting that found for the DAHs. Notably, the C-module, in which the C-for-N replacement is located, shows a strong preference for four or five attached carbons, either as two acyclic susbstituents or more preferably, as a five- or six-membered ring. The most active reported representative bears a 3,5-dimethyl substitution on the B-ring, a cyclohexyl group as the C-module, and a dioxan ring fused to the A-aryl group. The crystal structure of an AMK analog of methoxyfenozide shows a remarkable fit of its backbone atoms with those of a crystal structure for GS-E^{TM} (RG-102240, DAH: A = 2-ethyl, 3-methoxy; B = 3,5-dimethyl) (**Figure 22**) (Tice *et al*., 2003b). Thus, the doubly substituted backbone carbon,

isosteric to N(*t*-Bu), appears also to serve quite adequately as a conformational determinant.

3.4.9.4. Tetrahydroquinolines

The tetrahydroquinolines (THQ) are another distinctly different ecdysonergic chemotype for which an SAR is emerging. Investigators at FMC Corp., who made the initial discovery (Chaguturu *et al.*, 1999; Dixson *et al.*, 2000), have reported that representatives bind competitively with PoA to the EcR, and that they have a nanomolar affinity for the *Drosophila* receptor, exceeding their submicromolar affinity for HvEcR, the receptor from the tobacco budworm, *Heliothis virescens*. FMC Corp. has also demonstrated the compounds to be insecticidal. The optimized compounds bear small alkyl or halo groups in the *meta*- and/or *para*-positions of the D-ring and fluorine- or no substitution in the A- and C-rings. Subsequently at RheoGene, Smith *et al.* (2003) examined a designed library of THQs in an inducible gene regulation system based on AaEcR (from yellow fever mosquito, *Aedes aegypti*) in 3T3 cells and demonstrated that similarly optimized structures were nearly as potent as GS-E^{TM} as gene-switch elicitors, with induction levels reaching several hundred-fold above background (**Figure 23**). Published data do not quite yet allow definition of a THQ pharmacophore or a QSAR.

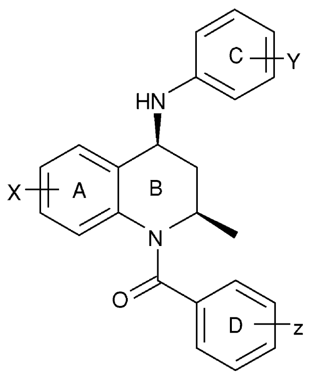

Figure 23 The tetrahydroquinoline (THQ) generalized structure.

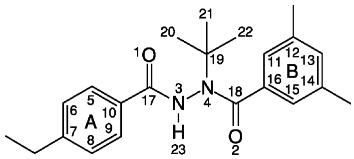
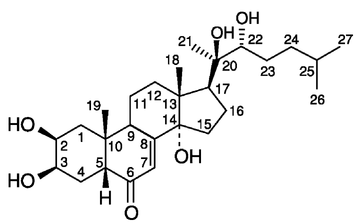


3.4.9.5. Other Chemotypes and Nonecdysonergic Effects



Other chemotypes reported to be E agonists or antagonists such as DTBHIB, maocrystal E, or the brassinosteroids, cucurbitacins, stilbenoids, phenylalkanoids, and harpagides are not yet sufficiently represented with an adequate span of potency for satisfactory application of QSAR. In one or two cases, true ecdysonergic properties remain to be adequately demonstrated. Only a preliminary SAR examination of the electrophysiological response of taste receptors to ecdysteroids has been conducted.

3.4.9.6. Interchemotype Comparisons

The DAH chemotype is striking not only owing to its extraordinary suitability as a crop protection agent, but also owing to the utter dissimilarity of its chemical structure to the natural ecdysteroids (**Table 5**).

Table 5 Diacylhydrazine and ecdysteroid structures, physiochemical properties, and numbering systems

	RH-75992 /tebufenozide	*Ponasterone A*
Shape	Globuar	Crescent
Volume (Å^3)	365	454
Surface area (Å^2)	465	633
Polar surface area (Å^2)	47	121
C log *P*	4.51	0.99
H bond donors	1	5
H bond acceptors	2	6
Effective rotatable bonds	2	5
Polarizability (μ)	7.79	3.72

Accordingly, interchemotype comparisons have been undertaken in the area of physiological properties, structural superimposition and model building and, ultimately, might take place in the arena of comparative EcR crystal structures containing alternate chemotypes. In EcR competitive binding studies and tissue activation, lepidopteran-optimized DAHs such as tebufenozide and methoxyfenozide match or exceed PoA in potency, but even the prototype RH-5849 compares favorably with the less active 20E (Dhadialla *et al.*, 1998; Nakagawa *et al.*, 2000b). Otherwise, for other insect orders, the DAHs are generally relatively weaker. The relationship is a bit less clear in engineered inducible gene regulation systems. In the VgEcR/RXR gene-switch, which is based on the *Drosophila* receptor (DmEcR), nine out of 21 tested DAH ligands showed an ability to actuate this ecdysteroid-responsive switch transiently transfected into CV-1 cells, albeit with considerably less potency than muristerone A (Saez *et al.*, 2000). On the other hand, Chinese hamster ovary cells stably transfected with the DmEcR-derived VgEcR/RXR switch and a β-galactosidase reporter responded to GS-E^{TM} at a level comparable to PoA and muristeroneA (MuA) (Carlson *et al.*, 2001a). In gene switches derived from lepidopteran EcRs, DAHs are generally superior to the steroids as ligands (Kumar *et al.*, 2002).

The geometrical relationship of ecdysteroids and DAHs is particularly interesting, not only because of their structural dissimilarity, but also owing to the compelling evidence, solidified by holo-EcR crystal structures, that the same binding cavity recognizes both chemotypes. This is the EcR paradox: the simultaneous high affinity for both the extended, polar, hydroxyl-laden ecdysteroids and the relatively compact, lipophilic, hydrogen bond donor-deficient diacylhydrazines.

An understanding of steroid–DAH superimpositions is greatly facilitated by an appreciation for the DAH and ecdysteroid conformational space. DAHs distribute into four conformational clusters based on the *E*- or *Z*-configuration of the amide bond. Each of these is described by a trivial nomenclature (**Figure 24**). Furthermore, each conformational cluster exists in two enantiomorphs, depending upon the *M*- or *P*-helicity of the N–N bond (**Figure 25**). Since the conformation-determining amide bonds are in the backbone of the structure, each of these clusters vary quite considerably in overall shape and potential superimposition with the ecdysteroids.

DAH conformational analysis by several investigators leads to the general conclusion that the extended, but especially the folded and stacked, conformations are more favorable than the hooked conformation. However, depending upon substitution pattern and calculation method, all four clusters can appear within as little as 4 kcal of the global minimum (Hormann *et al.*, 2003). More accurate calculations will certainly result with application of improved N–N torsional parameterization (Reynolds and Hormann, 1996; Chakravarty *et al.*, 1998). Perhaps owing to the fact that the folded conformation is frequently observed in crystal structures, all DAH–steroid superimpositions so far proposed, as well as all multidimensional QSAR studies, have focused on the folded conformation with either the *M*- or the *P*-helicity. The DAH conformation observed in the HvEcR crystal structure

is indeed a folded conformation of P-helicity (Billas *et al.* 2003).

The ecdysteroid conformational space varies primarily in the A-ring conformation and the trajectory of the side chain relative to the D-ring. The A-ring may take on a chair, half-chair, or twist-boat conformation; the chair conformation is found in the E crystal structure, which, in turn, is the basis for much of the modeling that has been performed. The C16/C17/C20/C22 and C17/C20/C22/C23 torsions are most conformationally-determinant; in the crystal structure, these take on values of 62.8° and 73.9°, respectively (Huber and Hoppe, 1965), thereby conferring a crescent shape to the entire molecule. Similar conformations often appear as the favored ones in 4D-QSAR studies, in which conformation is self-optimizing. Conformations incorporating a more acute bend at the core/side chain junction appear in at least one CoMFA study (Nakagawa *et al.*, 1998) and also for some weakly active steroids in 4D-QSAR studies. Satisfyingly, the PoA conformation observed in the HvEcR crystal structure shows an A-ring in the chair conformation and an overall crescent shape.

DAH/ecdysteroid superimpositions hypotheses have been derived from or analyzed by simple pharmacophore considerations (Shimizu *et al.*, 1997), perceived substructure analogy (Mohammed-Ali *et al.*, 1995; Sawada *et al.*, 2003a), conformational studies (Qian, 1996), homology model docking (Wurtz *et al.*, 2000), and multidimensional QSAR (Nakagawa *et al.*, 1995a, 1998; Hormann *et al.*, 2003). The latter two approaches potentially offer some degree of validation. The first superimpostion tested in a QSAR model relied on a set of 37 DAHs and six ecdysteroids tested in the previously mentioned *Chilo* integument assay. Overlaps were established by aligning the DAH carbonyl oxygens with O6 and O14 of the steroid, or alternatively, O14 and O20. Models were evaluated in part on the q^2 values which ranged from 0.393 to 0.472. The favored model ($q^2 = 0.472$, $r^2 = 0.892$, $s = 0.250$, five components) involved an O14/O22 alignment with the DAH B-ring oriented toward the side chain. Shimizu *et al.* (1997) later discovered that replacement of the DAH A-ring with simple C_5–C_6 alkyl chains resulted in structures with potency approaching that of tebufenozide in the *C. suppressalis* integument assay, and, considering the sensitivity of steroid potency to O22 configuration, hypothesized that DAH carbonyl alignments with O20 and O22 might result in superior superimpositions (Nakagawa *et al.*, 1998). CoMFA models of this superimposition type (**Figure 26**) compare favorably with models based on the O14/O22 alignment

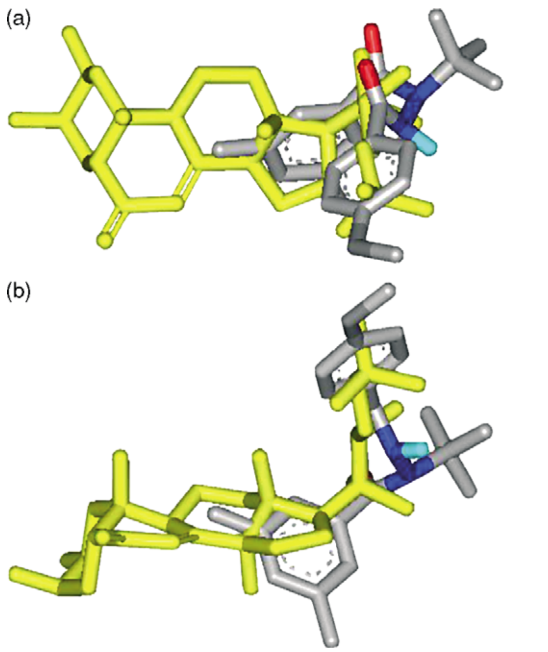

Figure 26 Favored superimposition for DAH–ecdysteroid CoMFA model of Nakagawa (1998). 20-Hydroxyecdysone and tebufenozide are depicted. (a) View from the β-face; (b) view towards the C6/C14 edge of the steroid. (Reproduced with permission from Nakagawa, Y., Hattori, K., Shimizu, B.-I., Akamatsu, M., Miyagawa, H., *et al.*, **1998**. Quantitative structure–activity studies of insect growth regulators XIV. Three-dimensional quantitative structure–activity relationship of ecdysone agonists including dibenzoylhydrazine analogs. *Pestic. Sci.* 53, 267–277.)

($q^2 = 0.359$–0.409 and 0.307–0.388, respectively), especially in view of the fact that 14OH is not necessary for receptor binding (Cherbas *et al.*, 1982). The analyses were performed with 56 DAHs and six ecdysteroids using *C. suppressalis* integument data as the target variable.

In another study, *Drosophila* B_{II} data for 97 DAHs and 66 ecdysteroids were fitted to eight different superimpositions, representing both *M* and *P* DAH enantiomorphs, using CoMFA and 4D-QSAR in a consensus strategy (Hormann *et al.*, 2003). The resultant QSAR models were evaluated on the basis of q^2 and test set r^2, using a test set comprising 19 DAHs and 33 ecdysteroids which had not been used in model construction. The best test set r^2 values, generally a more rigorous criterion of model quality than training set q^2, were obtained from a common superimposition ($q^2_{4D\text{-}QSAR} = 0.722$; $q^2_{CoMFA} = 0.607$, test set $r^2_{4D\text{-}QSAR} = 0.382$, test set $r^2_{CoMFA} = 0.428$) (**Figure 27**) which fortuitously resembled that obtained from a CtEcR homology model built from RAR-γ (Wurtz *et al.*, 2000). In this case, the DAH B-carbonyl aligns with the steroid B-ring carbonyl, but the DAH A-ring carbonyl does not

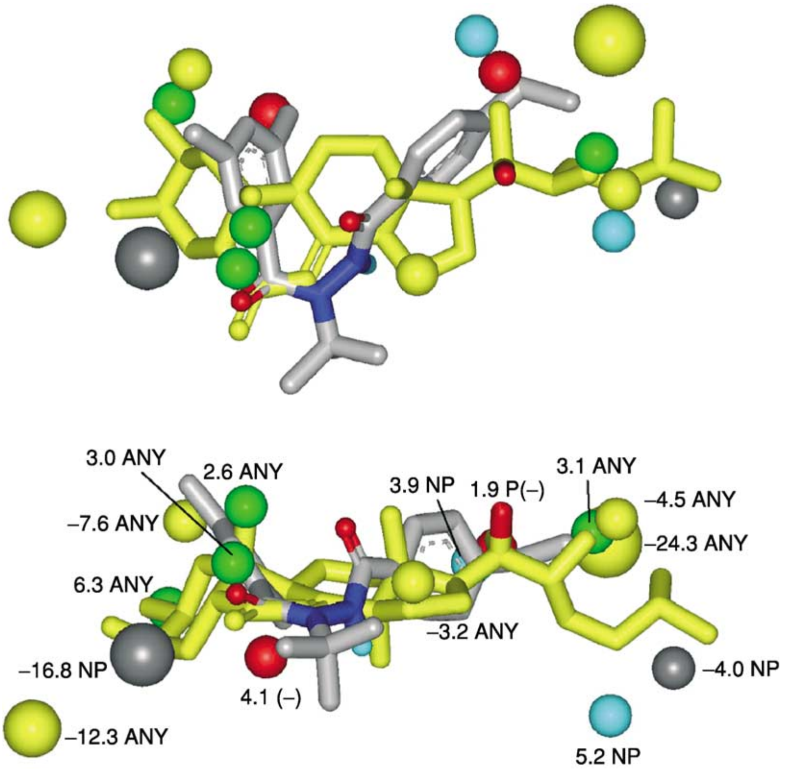

Figure 27 One of the favored DAH/ECD superimpositions depicted as its 4D-QSAR model relative to PoA and tebufenozide in their postulated active conformations with respect to each model. See explanatory text for **Figure 17**. (Reproduced with permission from Hormann, R.E., Dinan, L., Whiting, P., **2003**. Superimposition evaluation of ecdysteroid agonist chemotypes through multidimensional QSAR. *J. Comp. Aided Mol. Des. 17*(2–4), 135–153; © Kluwer Academic Publishers.)

align with any oxygen functionality. Another highly ranking superimpostion invoked a DAH carbonyl alignment with O20 of the steroid. None of these DAH/ecdysteroid superimposition hypotheses correspond to the overlap found for the HvEcR crystal structures (Billas *et al*., 2003). As previously alluded to, there is a structural reason to speculate that the excluding volume of M384 in H5 of DmEcR might possibly preclude this possibility altogether. Whatever the case may be, the HvEcR/BY-106830 structure offers a revealing answer to the EcR paradox – the recognition of widely disparate DAH and ecdysteroid chemotypes. In the HvEcR crystal structures, this is accomplished by (1) use of only partially overlapping loci (steroid side-chain and DAH B-ring/B–C=O/*t*-Bu), (2) use of only one common pharmacophore element (hydrophobe corresponding to distal portion of steroid side-chain and DAH B-ring/*t*-Bu), and (3) interaction with common hydrogen-bonding protein residues from substantially different positions (Y408 with steroid-20-OH/DAH-NH and T343 with steroid-14-OH/DAH B–C=O). It is becoming apparent that the complete set of pharmacophore elements recognized by EcR is much more expansive than those found in the ecdysteroids alone.

One must be mindful of the possibility of multiple binding modes across EcRs from different species, across analogs of the same chemotype, or even for a single ligand with respect to a single responsive EcR. Whether one adheres strictly to a crystal structure superimposition or speculates on alternate binding modes, superimposition exercises are useful because the resulting models can be used as virtual screens with quite different characteristics than scored docking.

Superimpositional studies of the alternate chemotypes are less advanced. The direct structural and SAR similarity of the AMKs strongly suggests that their steroid superimposition could be inferred from DAH considerations. The THQs, on the other hand, require an independent analysis. One illustrative possibility, generated from the genetic algorithm similarity program (GASP) algorithm, is shown in **Figure 28** (Jones *et al*., 1995). One might also speculate that the THQ A/D-rings or C/D-rings coincide with the DAH aryl rings.

3.4.9.7. Future Developments

QSAR methodology is important to ligand design because it enables conceptualization and succinct articulation of pharmacophoric design elements.

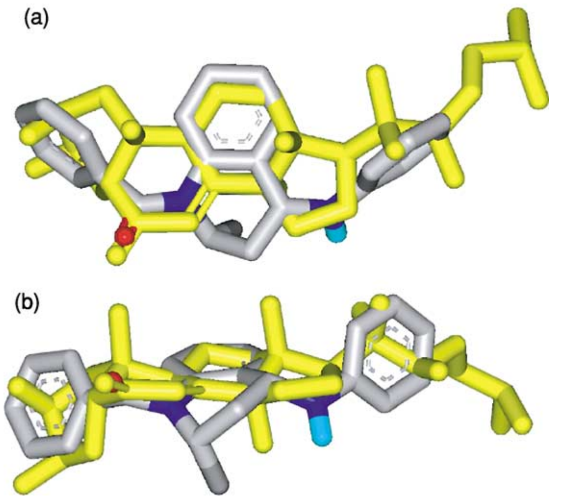

Figure 28 A possible THQ/ECD superimposition of the fully unsubstituted 2*R*,4*S*-THQ and PoA. (a) View from the β-face of PoA; (b) view towards the C6/C14 edge of PoA.

These design elements can take the form of localized physiochemical properties, hydrogen bonding potential, shape, molecular dynamics, and whole molecule properties. These features are frequently difficult or impossible to express in simple diagrams or prose, particularly in the area of multichemotype superimposition. Applied rigorously and creatively, QSAR can evoke novel perceptions of the ligands – perceptions that are useful for further design. These principles have held true for QSAR applied to ecdysteroid agonists.

Nevertheless, certain issues remain outstanding. Undersized training sets, narrow structural variation, and inadequate or imbalanced distribution across the target variable can lead to unstable models with limited explanatory power. The issue of model validation also requires more attention (Golbraikh and Tropsha, 2002). Models with low q^2 values or the absence of a test set leave the question of predictability completely unanswered and often in doubt. Moreover, even where test sets are applied, the test set selection may demonstrate only that the model is interpolative rather than extrapolative. The latter is preferred.

Examples of all of these compromising situations exist in the field of ecdysteroid agonist QSAR. To be sure, some of the aforementioned criteria have developed fairly recently as QSAR methodology has matured. Even applied imperfectly, the QSAR approach so far has exerted explanatory power and provided increased confidence during grueling synthesis programs. The indisputable mark of success will be a QSAR-based ligand design that would otherwise have been impossible. Multichemotype superimposition experiments may be headed in this direction. The demonstration that a structurally divergent active chemotype could be designed as a direct and unique consequence of a superimposition would be compelling indeed.

In the future, one may anticipate more extensive use of validating test sets and a more liberal application of consensus QSAR. The CoMFA/4D-QSAR studies open this door. Parallel models using topological descriptors or alternate variable selection and statistical methods may be especially effective in combination with multidimensional QSAR; a model using topological descriptors has been built on the ecdysteroid B_{II} data set (Golbraikh *et al.*, 2001). Additionally, judicious application of lateral QSAR using the same training sets, but different test organisms, may shed additional light on the cross-species selectivity question. One may also see improvements in multidimensional QSAR methodology which speak directly to the issue of multichemotype models.

The availability of an EcR binding domain crystal structure, in addition to answering numerous questions in structural biology, enables *de novo* ligand design. It is also possible that extracted protein information can be incorporated into ligand QSAR models (Santos-Filho *et al.*, 2001), which might be more reliably quantitative than pure docking. Both crystal structure and advanced receptor-independent QSAR models can be used as virtual screens to discover new ligands. In doing so, one must keep firmly in mind the possibility of unexpected or multiple binding modes, either within a single ligand-binding pocket or across species. It may turn out that protein dynamics simulations enhance the already illuminating perspective offered by static EcR crystal structures in explaining the level of receptor plasticity crucial for recognizing ligands of disparate structure.

3.4.10. Applications and Prospects

3.4.10.1. Insecticides

The wide diversity of chemistries that have been shown to interact with ecdysteroids receptors give hope that further commercially viable compounds can be developed as effective and selective insecticides. The lead given in this area by the DAHs is very encouraging. These compounds are chemically simple, effective, nontoxic to vertebrates, and even show some selectivity towards particular insect orders (Hsu *et al.*, 1997; Dhadialla *et al.*, 1998; Carlson, 2000; Carlson *et al.*, 2001b). The discovery of the DAHs was somewhat serendipitous, but the development of further classes of ecdysteroid signaling pathway-active compounds can be facilitated

through mechanism-based assays, QSAR, molecular modeling, and virtual screening. Prior to the identification of the DAHs, it was questioned whether ecdysteroid agonists would make effective insecticides, since it was expected that such compounds would only have an effect at the next molt. In the event, the fact that affected insects do not immediately die is not a problem because a further effect of the ecdysteroid agonist is to bring about a cessation of feeding. Ecdysteroid antagonists might be expected to be effective against pest species where the adult is the destructive stage or where reproductive disruption is sought. However, as our understanding of the pleiotropic physiological consequences of ecdysteroid (ant)agonists is still very incomplete, we should not exclude the possiblitiy that ecdysteroid antagonists may also be effective against larval insects or embryos.

3.4.10.2. Genetic Modification of Ecdysteroid Levels in Crop Plants

Very few crop species accumulate ecdysteroids. Only spinach (*Spinacia oleracea*; Chenopodiaceae) and quinoa (*Chenopodium quinoa*; Chenopodiaceae) accumulate significant amounts (Dinan, 1992, 1995b). However, available evidence indicates that most, if not all, higher plant species possess the genetic capacity to produce ecdysteroids, but that the pathway is downregulated (Dinan *et al*., 2001d). If this is true, this will considerably facilitate the elevation of ecdysteroid levels in crop species, as alteration of the regulation will result in changes in ecdysteroid level. This could require alteration of only one gene, rather than the incorporation of a series of genes for the entire biosynthetic pathway. As an absolute prerequisite to the genetic modification of ecdysteroid levels in crop species, it is necessary that the biosynthetic pathway for phytoecdysteroids should be elucidated. Significant progress is now being made in this area using hairy root cultures of *A. reptans* (Fujimoto *et al*., 2000), which produce ecdysteroids in large amounts and allow stable isotope-labeled precursors to be incorporated in high yield permitting analysis of ecdysteroidal products by ^{13}C NMR. The generality of the *Ajuga* pathway(s) will need to be assessed and the regulation of the pathways determined in order to identify the step(s) which are downregulated in nonaccumulating species. Ecdysteroid-accumulating lines of crop species could be generated by genetic engineering approaches or by traditional plant breeding techniques. Ultimately, it should be possible to modify the profile of ecdysteroids present in crop plants to maximise resistance against even polyphagous pest species which possess particular detoxification mechanisms against common major ecdysteroids (e.g., 22-acylation of 20E) and/or to elevate levels of ecdysteroids of higher biological activity (e.g., PoA). The very low vertebrate toxicity (and even benefit as nutritional supplements) and lack of taste of ecdysteroids would mean that phytoecdysteroid accumulation need not be restricted to the portions of the plant not to be consumed.

3.4.10.3. Gene Switching Elicitors

Engineered inducible gene expression systems are gaining research attention and technological significance. Gene switches permit the temporal and/or spatial expression of transfected genes, with potential application in medicine (gene therapy, tissue engineering, biotherapeutic protein production), agriculture (crop protection, yield enhancement, nutritional enhancement, pharmaceutical production) and in basic research for investigation of gene function (proteomics and drug lead discovery). Several different approaches are being developed (Fussenegger, 2001) and the use of native or hybrid ecdysteroid receptors with ecdysonergic ligands is one of the current forerunners in the field. The elicitor should be effective at low concentrations and should be target-specific (i.e., nontoxic). For medical applications, the elicitor should be nonallergenic and preferably orally available. The elicitor can also affect dynamic properties of the gene switch such as response time, cycling, dynamic range, maximum response, span of the dose-response curve, and tissue specificity. These properties should be tailored to the specific application. Ecdysteroids and DAHs, which, taken together, span a wide range of physiochemical properties, and are both highly promising chemotype candidates for many gene-switch applications.

The gene-switch potency, absorption, distribution, and known pharmacological properties of the ecdysteroids are favorable toward most uses of a gene switch. On the other hand, metabolism and elimination may be mitigating factors. When native or hybrid ecdysteroid receptors are transfected into mammalian, plant or yeast cells, the EcRs possess altered ecdysteroid specificity and potency. In some cases, 20E is hardly active at all and PoA and MuA are required at concentrations 100-fold higher than in insect systems. More extensive SAR or even QSAR studies could assist identification of the most potent ecdysteroids for these systems. A detailed discussion of ecdysteroid-regulated gene switches is beyond the scope of this review, but has been reviewed elsewhere recently (Lafont and Dinan, 2003).

The properties of DAHs that are quite favorable to gene switch applications are potency towards

lepidopteran EcRs, metabolic stability, chemical simplicity, and absence of toxicity. Available data suggest that absorption and distribution properties may be acceptable for pharmaceutical applications. However, solubility is potentially a barrier to be overcome. It remains to be seen if the DAH physical properties are an issue for agricultural gene switch applications in which plant uptake requirements may differ from those needed for the already successful insecticidal applications. An alternative DAH (GS-E^{TM}) (**Figure 6**) has been developed for use with mammalian cells. QSAR has been brought to bear on DAH potency in a mammalian cellular EcR-based gene switch system (Hormann *et al.*, 2002), and should aid future studies that pertain to pharmacokinetics.

Orthogonal gene switches, that is to say, multiple parallel switches which can be actuated simultaneously, noninteractively, and independently, would constitute a significant enhancement to the field of engineered gene regulation. A major potential benefit of EcR systems is their inherent orthogonality to the corresponding transcriptional machinery of the mammalian host. A concomitant liability, however, is the potential for immunogenicity. Likewise, ecdysteroids are not regarded as normal, interactive components of mammalian cells and may have a natural built-in orthogonality. However, the ecdysteroids are present in certain plants as phytoecdysteroids, can be present in the human diet, and may later turn out to have unacceptable pleiotropoic effects. For purposes of orthogonality, the DAHs look attractive. Certainly, the order-specificity of DAHs can be exploited to develop switches for different hybrid ecdysteroid receptors in the same system. For representative ecdysteroids, an otherwise ecdysteroid-responsive EcR has been rendered ecdysteroid-refractive by site-directed mutagenesis, auguring well for orthogonal systems which also utilize a DAH elicitor in a parallel channel, as has been addressed at RHeoGene, L.L.C. (Kumar *et al.*, 2002).

3.4.10.4. Human Health Preparations and Animal Food Supplements

The effects of ecdysteroids on mammals have recently been reviewed (Lafont and Dinan, 2003), to which the reader is referred for more extensive treatment of this topic. As a consequence of the reputed anabolic effects of ecdysteroids on animals, a large number of ecdysteroid-containing preparations are now available for use by sportsmen and body-builders. While there is evidence for the positive anabolic effects of ecdysteroids on Japanese quail (Koudela *et al.*, 1995; Sláma *et al.*, 1996) and pigs (Selepcova *et al.*, 1993; Kratky *et al.*, 1997), the effects are not dramatic (ca. 15% increase in body mass over controls). Ecdysteroids may also improve physical performance, as demonstrated on rats (Chermnykh *et al.*, 1988). Evidence has been provided for effects of ecdysteroids on cellular proliferation, protein synthesis, glucose metabolism, lipid metabolism, nerve function, hepatic function, cardiovascular function, renal function, and the immune system, indicating that ecdysteroids might contribute to the relief of conditions such as diabetes, hypercholesterolemia, wound healing, mental disorders, myocardial arrhythmia, inflammations, etc. (review: Lafont and Dinan, 2003). All these aspects need further study and verification, but the lack of toxic dose required to kill 50% of the organism ($LD_{50} > 6\,g\,kg^{-1}$), androgenic or (anti)estrogenic effects make pharmacological applications of ecdysteroids feasible and potentially attractive.

3.4.10.5. Improvement of Silk Yields

Exogenous ecdysteroids fed to larvae of the silkworm *Bombyx mori* at certain stages of development enhance synchronous development of the larvae and, when coadministered with a juvenile hormone analog, significantly elevate the yield of silk obtainable from the cocoon (Chou and Lu, 1980; Ninagi and Maruyama, 1996). Such treatments have considerable potential to improve the efficiency of silkworm-rearing by Asian farmers, especially since the hormonal treatments could be based on extracts of appropriate indigenous plant species (Chandrakala *et al.*, 1998).

3.4.10.6. Endocrine Disruption

Although it is recognized that endocrine disruption in invertebrates may be a potentially serious problem, many of the necessary experimental tools are not available for research in this area. The many gaps that still exist in our knowledge of invertebrate endocrinology limit the ability to interpret the toxic effects of exogenous chemicals. Even for the insects, where quite extensive endocrinological information is available for a number of model species, they do not correspond to aquatic species or to the sentinel species one would wish to use to monitor for EDCs. Thus, it is to be expected that there will be a revival in interest in hormone biochemistry for environmentally relevant species to provide baseline information against which exposed insects can be compared. Further, with the sequencing of the *D. melanogaster* genome and the development of DNA arrays, it is to be expected that the influence of exogenous chemicals on gene expression will be investigated more extensively.

3.4.10.7. QSAR and Molecular Modeling

If we are to understand the role of phytoecdysteroids in deterring insect predation, the QSAR/modeling approach should be extended to more analogs and to more species and to the SAR of the deterrent antifeedant/toxic effects of ecdysteroids. This would go some way to explain the diversity of phytoecdysteroid structures in plants. The pharmacological effects of ecdysteroids (almost exclusively 20E) on mammals are only now being accepted and it seems that there are many potential beneficial effects. In the future, it will be helpful to conduct QSAR and docking/scoring studies to identify the most effective analogs. In the area of gene switching using ecdysteroids as analogs, SAR will be important not only because hybrid ecdysteroid receptors in mammalian cells have altered specificities, but also because ligands will need to be tailored as specific elicitors for multiplex systems expressing several receptor types simultaneously, in order to enable selective activation of their regulated genes.

Acknowledgments

We are grateful to Y. Nakagawa for molecular structures of diacylhydrazine–ecdysteroid superimpositions. Research conducted at Exeter University was supported by the BBSRC, Rohm & Haas Co., RheoGene Inc., Astra-Zeneca plc, EU-INTAS and the Leverhulme Trust.

3.5 The Ecdysteroid Receptor

V C Henrich, University of North Carolina-Greensboro, Greensboro, NC, USA

3.5.1. Overview

3.5.1.1. Molecular Identity of the Insect Ecdysteroid Receptor

The morphogenetic events associated with insect development are largely triggered by the action of a single class of steroid hormones, the ecdysteroids (see **Chapter 3.3**).[1] Among all insect orders examined so far, it has been established that the ecdysteroid-induced orchestration of molting and metamorphosis is mediated by a heterodimer comprised of the ecdysone receptor (EcR; Koelle *et al.*, 1991) and Ultraspiracle (USP; Oro *et al.*, 1990; Shea *et al.*, 1990; Henrich *et al.*, 1990) that is stabilized by 20-hydroxyecdysone (20E) and which recognizes specific promoter elements in the insect genome to regulate transcription (Yao *et al.*, 1992, 1993; Thomas *et al.*, 1993). Both proteins belong to a superfamily of nuclear receptors which mediate transcriptional responses to steroids and other lipophilic molecules (Blumberg and Evans, 1998) (see **Chapter 3.6**). Recently, a second ecdysteroid-signaling pathway involving USP and another nuclear receptor DHR38 (Sutherland *et al.*, 1995) has been discovered (Baker *et al.*, 2003).

The insect EcR is a distant relative of the vertebrate farnesol X receptor (FXR; Forman *et al.*, 1995) and LXR (Willy *et al.*, 1995). EcR was first identified in the fruit fly, *Drosophila melanogaster*, and has since been found in several insects, in the ixodid tick (*Amblyomma americanum*; Guo *et al.*, 1997) and in the fiddler crab (*Uca pugilator*; Durica *et al.*, 2002). No functional EcR ortholog has been reported outside the arthropod phylum (Bonneton

[1]Ecdysteroids refers to the family of ecdysteroids including natural and artificial steroids. Individual forms, including the classic active "molting hormone," 20-hydroxyecdysone (20E, formerly β-ecdysone), will be specified throughout the chapter, as will its precursor, ecdysone (formerly α-ecdysone). Ecdysteroid agonists refers to molecules which are not steroidal, but which are capable of inducing one or more insect EcR genes in a given experimental regime.

et al., 2003) (see **Chapter 3.6**). The Ultraspiracle (USP) protein is an ortholog of the retinoid X receptor (RXR), which in turn is a heterodimeric partner for several other nuclear receptors (Mangelsdorf *et al.*, 1990; Oro *et al.*, 1990). Among noninsect invertebrates, an RXR ortholog has been reported from *A. americanum* (Guo *et al.*, 1998), *U. pugilator* (Chung *et al.*, 1998), and the parasitic nematode, *Dirofilaria immitis* (Shea *et al.*, 2004). RXR is widely found in humans and other vertebrates, reflecting its early evolutionary origins (see **Chapter 3.6**). Both EcR and USP have diverged evolutionarily among the insect orders (see **Chapter 3.6**), indicating that the functional properties of EcR and USP have also diverged among them.

3.5.1.2. Historical Perspective

The pursuit of the insect ecdysteroid receptor and its activities has led to a convergence of several basic and applied research disciplines. The ability of a single steroid hormone to induce widespread and coordinated changes in gene transcription has attracted basic scientists interested in the mechanistic basis of its variable gene and cellular action. For insect biologists, the diversity of developmental responses triggered by ecdysteroids among the insect orders reveals the essential importance of this process for understanding the evolutionary diversity and adaptability seen among individual insect species. In turn, the variety of responses among the insect orders has led to attempts to disrupt ecdysteroid receptor action with species-specific agonists and antagonists such as the bisacylhydrazines (Wing, 1988) for insecticidal purposes (Dhadialla *et al.*, 1998, and references therein; see **Chapter 3.4**). Finally, because ecdysteroids exert no harmful effects in humans and other organisms (see **Chapter 3.4**), the ecdysteroid receptor is now viewed as a potential inducer of beneficial transcriptional responses in plant and animal cells. Much of the work on ecdysteroid action that was reported prior to 1985 appeared in the previous edition of this series and will not be repeated here (Riddiford, 1985; O'Connor, 1985; Yund and Osterbur, 1985), except for those early events which have had an obvious bearing on continuing investigations.

The effects of ecdysteroids upon gene transcriptional activity became apparent through studies of the effects of "molting hormone," 20E, on the polytene chromosomes of insects such as *D. melanogaster* and *Chironomus tentans* (midge). Puffing was first reported in 1933 in *D. melanogaster* by E. Heitz, and in the early 1950s Wolfgang Beermann performed seminal work on puff changes in *C. tentans*. Later, Ulrich Clever demonstrated that the insect "molting hormone" induced puffing changes and thus reported the first evidence that steroid hormones act directly upon the transcriptional activity of specific target genes, now regarded as a central feature of steroid hormone action in all animals. A variety of biochemical studies also established the presence of a protein in cellular extracts that binds to ecdysteroids, further indicating that an intracellular receptor mediates the transcriptional response (O'Connor, 1985; Yund and Osterbur, 1985, and references therein).

Conceptually, the polytene chromosomes can be viewed as an *in situ* expression microarray (**Figure 1**), since the puff sites disclose the transcriptional activity of specific genes (by chromosomal location rather than by sequence). This natural array has the added and unique benefit of showing temporal changes in puff size that roughly indicate continuous changes in transcriptional rate. Hans Becker noted in 1959 that "early" puffs appear when incubated with the ecdysteroidogenic ring gland and regress as other "late puffs" appear (Becker, 1959). Ulrich Clever and Michael Ashburner later showed that blocking the protein translation of early puff RNAs with cycloheximide treatment prevents the regression of some early puffs, and simultaneously prevents the appearance of many late puffs (Asburner *et al.*, 1974). From these findings, Ashburner postulated that an intracellular

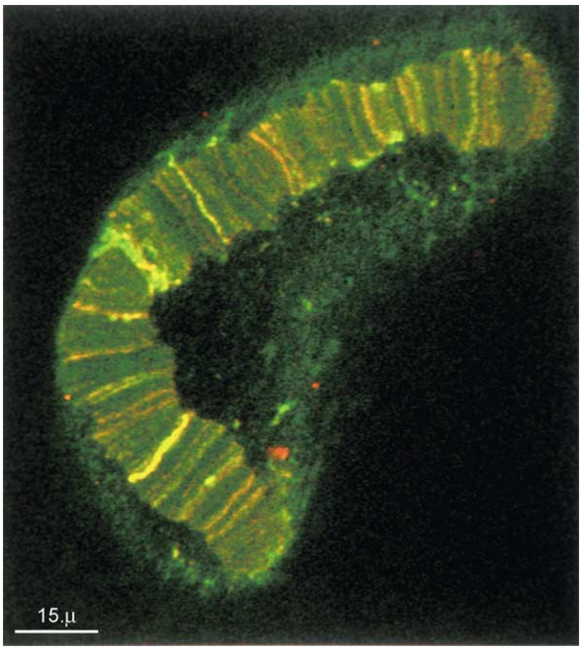

Figure 1 Prepupal chromosome III from *Chironomus tentans* labeled with antibodies against EcR (green) and RNA polymerase II (red). Yellow signals indicate colocalization of the two antibodies. Green signal is a fixation artifact. See Wegmann *et al.* (1995) for methods. (Photograph courtesy of Markus Lezzi.)

ecdysteroid receptor directs a transcriptional response at early puff sites in the presence of 20E. Further, the early puff gene products regulate the appearance of later puffs and also feedback to repress their own expression. This original model for ecdysteroid action has proven remarkably durable over the years, though it is often overlooked that several puffs described by Ashburner have not been placed within the regulatory hierarchy and that some features of the model have not yet been pursued at the molecular level.

The role of a receptor was also implicated by the identification of an ecdysone response element (EcRE) in the ecdysteroid-inducible promoter of the 27 kDa heat shock protein (*hsp27*) of *D. melanogaster* (Riddihough and Pelham, 1987). The palindromic inverted nucleotide repeat sequence of this ecdysteroid receptor target resembles the motifs that at the time of its discovery were associated with a growing class of nuclear receptors for several vertebrate hormones, including the glucocorticoids and estrogen (Hollenberg *et al.*, 1985; Green *et al.*, 1986), raising anticipation that the ecdysteroid receptor is evolutionarily conserved, just as the process of steroid action on transcriptional activity is mechanistically conserved.

Much of the progress made on the molecular genetic basis of ecdysteroid action can be traced to 1968 when, during a sabbatical at CalTech, David Hogness met Ashburner, who was a postdoctoral associate there. Hogness later visited the laboratory of Beermann at Tubingen, and decided to identify the "puff" genes targeted by ecdysteroid action. The conviction to this goal was strong enough that Hogness isolated overlapping genomic DNA segments over a span of several hundred kilobases to find them. His laboratory successfully "walked" through the chromosomal region associated with two early puff genes using this positional cloning approach (Burtis *et al.*, 1990; Segraves and Hogness, 1990). One of the early puff genes, E75,[2] encodes a member of the nuclear hormone receptor superfamily (Segraves and Hogness, 1990), as defined by two cysteine–cysteine zinc fingers that are responsible for the receptor protein's recognition of specific promoter elements.

[2]The puff sites in *Drosophila melanogaster* were originally identified by their cytological location among the 102 subintervals arbitrarily delineated across the sex chromosome (X or chromosome 1, subintervals 1–20) and three autosomes (chromosome 2, subintervals 21–60; chromosome 3, subintervals 61–100, chromosome 4, subintervals 101–102) that comprise the *D. melanogaster* genome. The puffs are further designated as E (early or early-late) or L (late) based on their temporal appearance after 20E incubation.

E75, several other ecdysteroid-responsive gene products in *Drosophila*, and numerous other superfamily members are "orphan receptors," that is, they carry the zinc finger configuration but do not mediate transcriptional activity through any known ligand. When E75 was used as a probe to screen a cDNA library, one of the recovered candidate clones proved to be the *D. melanogaster* ecdysone receptor gene (*Dm*EcR; Koelle *et al.*, 1991), and a functional receptor was also recovered by biochemical purification from a *Drosophila* embryonic cell line (Luo *et al.*, 1991). In reality, EcR dimerizes with a second nuclear receptor, Ultraspiracle (*Dm*USP; Yao *et al.*, 1992, 1993; Thomas *et al.*, 1993), whose structural resemblance to the vertebrate RXR suggests its conservation as a heterodimeric partner for EcR. The recovery of EcR, USP, and orphans such as E75 inspired a more exhaustive search for nuclear receptors in *D. melanogaster*, and the annotated genome now lists 21 nuclear receptors. Among them, only EcR unambiguously interacts physically with an activating ligand, though there is evidence that USP binds to juvenile hormone (Jones and Sharp, 1997; Jones *et al.*, 2001).

The recovery and characterization of EcR, USP, other orphan receptors, and various ecdysteroid-inducible targets in other insects has proceeded at a quickening pace in recent years, and, along with it, a proliferation of DNA probes and antibodies have been developed to examine these players. Several insect researchers have actively identified orthologs for EcR and USP and its puff gene targets so that a rapidly expanding body of comparative information is appearing in the literature. The abundance of information accumulated in the *Drosophila* system has heavily influenced mechanistic interpretations of ecdysteroid action, though it is apparent from the comparative studies done so far that ecdysteroid action at the developmental level varies among insect species, consistent with their wide range of adaptations to the environment. Complete EcR and USP sequences have so far been reported for a few dozen species among four of the insect orders (Diptera, Lepidoptera, Orthoptera, and Coleoptera) and two other arthropod classes. If the variety of results obtained from these studies provide any indication, then only a fraction of the potential information concerning the ecdysteroid receptor has so far been retrieved and assimilated.

3.5.1.3. Chapter Organization

The straightforward thesis of the ecdysteroid hierarchy based on the chromosomal puff response seems to contrast with the complexity found in many

in vivo experiments. It is apparent that ecdysteroid responsiveness varies widely by tissue or cell type, species, incubation conditions, developmental time, activating ligand, ligand concentration, and treatment duration, presumably because the functional capacity of the receptor itself varies in these regimes. Nevertheless, several common and conserved themes have emerged from this work that are valuable not only for insect biologists, but also for other geneticists, cell biologists, and endocrinologists.

The organization of this chapter is based largely on the criteria by which the EcR of *D. melanogaster* was originally defined: (1) the deduced EcR amino acid sequence includes the zinc fingers and ligand-binding domain helices that typify nuclear receptors, (2) extracts of cells expressing EcR bind to ^{125}I-iodoponasterone and this binding disappears with the addition of anti-EcR antibodies, (3) insect cellular extracts carry a protein that binds specifically to an *hsp27* EcRE and this binding disappears in the presence of anti-EcR antibodies, (4) ecdysteroid-inducible transcription is restored to an ecdysone-insensitive *Drosophila* cell line by transfecting the cells with EcR cDNA, and (5) the pattern of spatial and temporal expression of EcR during premetamorphic development is consistent with its role as a mediator of the ecdysteroid response (Koelle *et al*., 1991).

This chapter will examine the information gathered about the ecdysteroid receptor at three levels, and provide brief descriptions and references for the tools used to undertake those experiments. First, the receptor will be viewed as a structural entity, with particular emphasis on the sequence characteristics of EcR and USP as well as their biophysical and biochemical properties. These studies build upon the first three properties noted for EcR in its original characterization. Second, and as in the original report, the transcriptional function of the ecdysteroid receptor will be examined, with particular regard to its interactions with ligand, other protein factors, and promoter elements. This section will also describe a few of the ecdysteroid-inducible systems which have been developed for various applications. Third, the ecdysteroid receptor will be viewed from a cellular and developmental perspective *in vivo*, with special emphasis on the spatial and temporal diversity of ecdysteroid-mediated action, along with the approaches used to address these questions. Finally, the chapter will offer a prognosis concerning important and unresolved problems surrounding ecdysteroid action via its receptors, along with possible experimental technologies and strategies that might clarify them.

3.5.2. Ecdysteroid Receptor Structure, Biophysics, and Biochemistry

3.5.2.1. Domain Organization and Amino Acid Alignment

Both EcR and USP belong to the superfamily of nuclear receptors first described for several steroid hormones and vitamins among the vertebrates. Like their evolutionary counterparts, EcR and USP are structurally modular, that is, they are composed of distinct domains responsible for specific molecular functions (**Figure 2**). Individual domains are at least partially autonomous in their function, since domains of different nuclear receptors can be swapped to create structural and functional chimeras. Chimeras derived from the EcR and USP of different insect species have been used to compare and differentiate their functional capabilities (e.g., Suhr *et al*., 1998; Wang *et al*., 2000; Henrich *et al*., 2000).

The basic organization of nuclear receptors has been described extensively in other reviews, and will be examined here exclusively in terms of the functional features found in insects and associated with each of the domains: (1) the N-terminal (A/B) domain through which nuclear receptors interact with other transcriptional factors, (2) the DNA binding domain (DBD) or C domain which is responsible for the receptor's recognition of specific DNA response elements in the genome and which is comprised of two cysteine–cysteine zinc fingers that define proteins as members of the nuclear receptor superfamily, (3) the hinge region (D domain), which has been implicated in ligand-dependent heterodimerization along with the E domain, nuclear localization, and DNA recognition, (4) the E- or ligand-binding domain (LBD), which is usually comprised of 12 alpha-helices that form a ligand-binding pocket, and (5) the F domain, which is found as a nonconserved sequence in all of the insect EcRs but not in any known USP or RXR sequence.

3.5.2.1.1. The A/B domain This domain is sometimes referred to as the *trans*-activation domain because this portion of the nuclear receptor interacts with the cell's transcriptional machinery and is responsible for a ligand-independent transcriptional activation function (AF1). The A/B domain tends to be variable among nuclear receptors, though there is modest similarity in this portion of EcR and USP among insect species. In several species, multiple isoforms of EcR and/or USP with different A/B domains arise through the activity of alternative promoters and/or alternative pre-mRNA splicing. The occurrence of multiple isoforms for EcR and

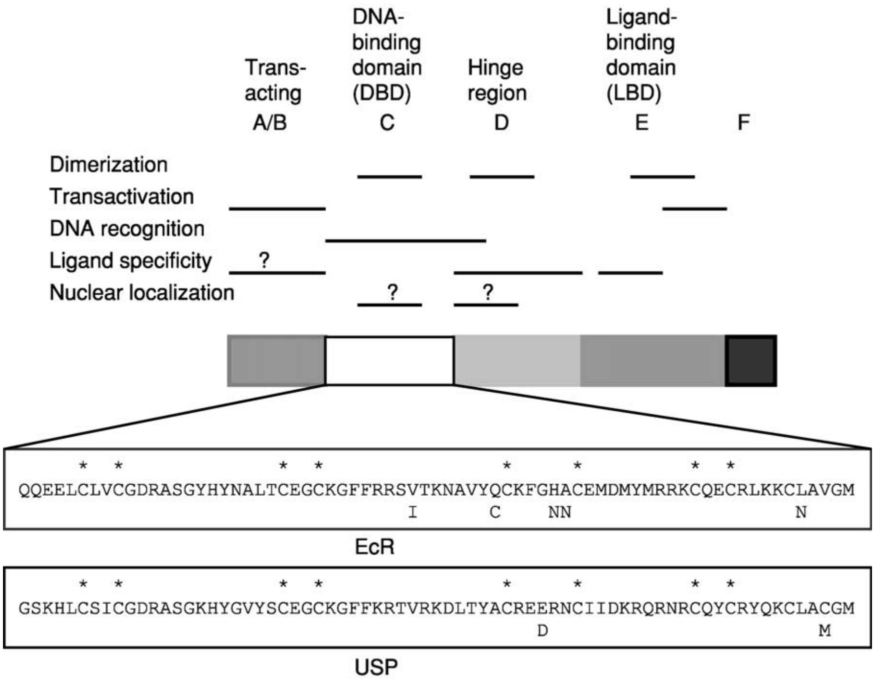

Figure 2 Domain organization of nuclear receptor superfamily members. Bars denote regions of the receptor associated with specific subfunctions or suspected subfunctions (as indicated with a ?). Boxed regions indicate consensus amino acid sequences for the DNA-binding domain of insect EcR and USP based on Bonneton *et al.* (2003). Asterisks (*) indicate positions of two sets of four cysteines which ligand to zinc ion to form each of the two zinc fingers.

USP does not follow any apparent pattern and therefore does not seem to be tied to an obvious evolutionary mechanism. For instance, so far only the *Dm*EcR gene among insects encodes three isoforms (A, B1, and B2; Talbot *et al.*, 1993). Among cyclorapphous flies the Mediterranean fruit fly (*Ceratitis capitata, Cc*) EcR gene specifies both the A and B1 isoforms (Verras *et al.*, 2002), whereas only the B1 isoform has been found so far in the sheep blowfly (*Lucilia cuprina, Lc*) genome (Hannan and Hill, 1997).

Among other Diptera, the mosquito (*Aedes aegypti, Aa*) EcR encodes the A and B1 isoforms (Wang *et al.*, 2002), but the midge (*Chironomus tentans,Ct*) encodes only the B1-like isoform (Imhof *et al.*, 1993). The same variable pattern is found among the lepidopteran species. The corn earworm (*Heliothis virescens, Hv*; Martinez *et al.*, 1999a) has only EcR-B1, whereas the spruce budworm (*Choristoneura fumiferana, Cf*; Perrera *et al.*, 1999a), the rice stem borer (*Chilo suppressalis, Cs*), the tobacco hornworm (*Manduca sexta, Ms*; Jindra *et al.*, 1996), and the silkmoth (*Bombyx mori, Bm*; Swevers *et al.*, 1995; Kamimura *et al.*, 1997) express both an A and B1 isoform. An A and B1 isoform of EcR has also been recovered from the mealworm (*Tenebrio molitor, Tm*) genome (Mouillet *et al.*, 1997) and a single EcR isoform has been recovered from the migratory locust (*Locusta migratoria, Lm*; Saleh *et al.*, 1998). The most complex EcR gene organization is found in a noninsect species, *A. americanum*, wherein at least three A/B isoforms have been identified, each of which resembles the *D. melanogaster* A isoform sequence (Guo *et al.*, 1997). The functional properties of the insect EcR isoforms and their distinct developmental roles will be discussed later in the chapter, though it is noteworthy that the B2 isoform uniquely associated with *D. melanogaster* is also the most efficient for rescuing larval development in EcR homozygous mutants that would otherwise die during embryonic development (Li and Bender, 2000). This observation simultaneously highlights the possible uniqueness of the fruit fly EcR and the potential significance of the A/B domain for comparison among the insects.

In one species, *C. tentans*, multiple USP isoforms differing in their A/B domain occur along with only a single EcR isoform (Vogtli *et al.*, 1999). The migratory locust (*Locusta migratoria; Lm*) also expresses multiple USP isoforms along with the single EcRB1 isoform found so far, though the USP variants do not arise from differential splicing in the A/B domain (Hayward *et al.*, 1999, 2003). Along with two EcR isoforms, two USP isoforms exist in *A. aegypti* (Kapitskaya *et al.*, 1996), *M. sexta* (Jindra *et al.*, 1997), and *B. mori* (Tzertzinis

et al., 1994). Two RXR/USP isoforms also exist in *A. americanum*, along with its three EcR isoforms (Guo *et al.*, 1998). Other complete USP sequences have been reported for *L. cuprina* (Hannan and Hill, 2001) and *C. fumiferana* (Perera *et al.*, 1998).

3.5.2.1.2. The C domain or DNA-binding domain (DBD) The members of the nuclear receptor superfamily are defined by a 66–68 amino acid region known as the cysteine–cysteine zinc finger (**Figures 2 and 3**). The EcR DBD closely resembles the vertebrate FXR, and both EcR/USP and FXR/RXR recognize a palindromic inverted repeat sequence separated by a single nucleotide (IR1); the *hsp27* EcRE follows this arrangement. A consensus sequence based on the investigation of several functional IR1 elements is: 5′-PuG(G/T)T(C/G)A(N)TG(C/A(C/A(C/t)Py (Antoniewski *et al.*, 1993). As will be noted later, the EcR/USP complex is also capable of recognizing direct repeat elements (Antoniewski *et al.*, 1996; Vogtli *et al.*, 1998). The DBD amino acid sequence is highly conserved among the Diptera and Lepidoptera, but specific residues are substituted in the EcR DBD of other insects (Henrich and Brown, 1995; Bonneton *et al.*, 2003) (see **Chapter 3.6**).

3.5.2.1.3. The D domain or hinge region The D domain includes the amino acids which lie between the zinc fingers and the ligand binding domain (LBD). Portions of this region are highly conserved among all the insect EcRs, including a T-box motif that plays a role in DNA recognition (Devarakonda *et al.*, 2003; **Figure 3**) and an A-box, a helical structure that is essential for high affinity recognition of a DNA response element (Niedziela-Majka *et al.*, 2000). The D region of EcR is also essential for ligand dependent heterodimerization with USP (Suhr *et al.*, 1998; Perera *et al.*, 1999b). The USP hinge region includes a highly conserved

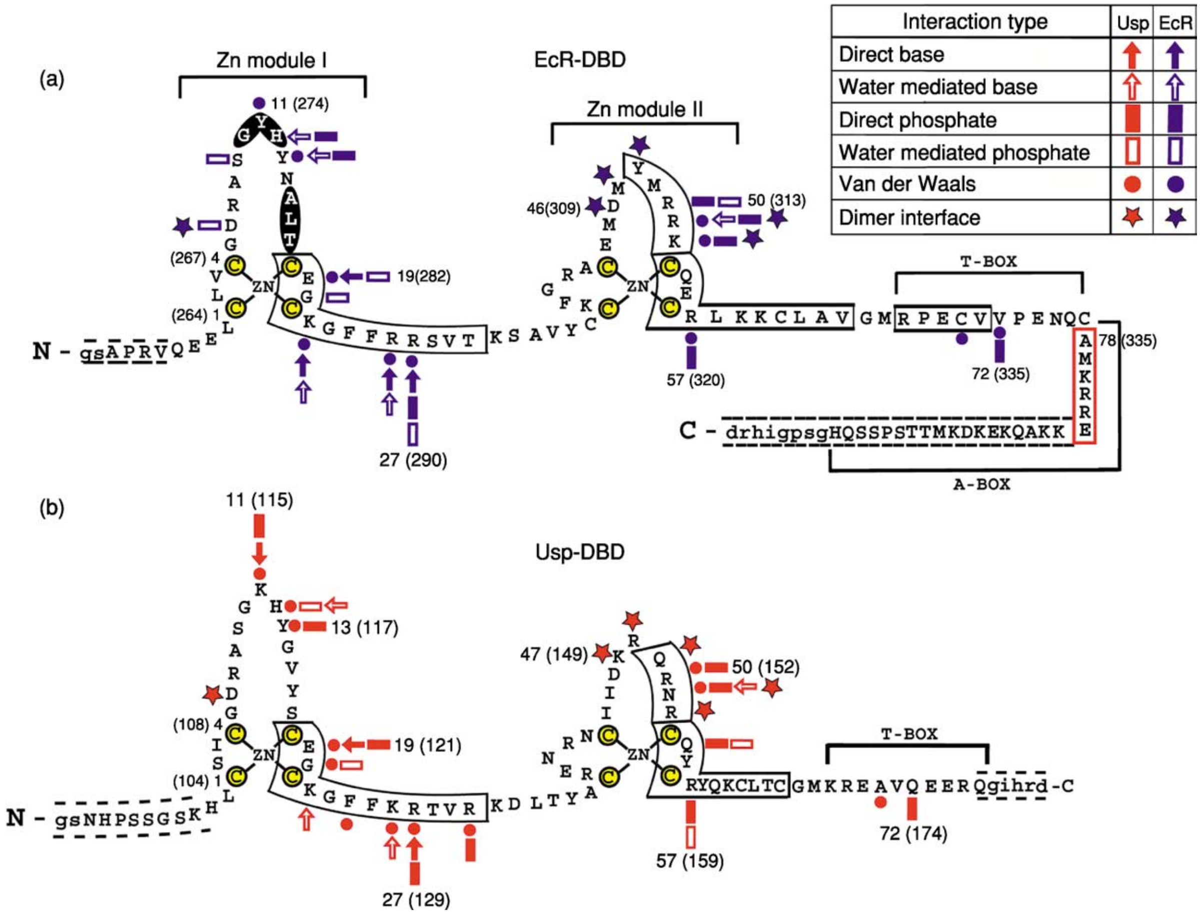

Figure 3 The protein constructs used for a crystallization study, designating amino acid contact sites with noted DNA interactions. (a) Sequence of *Drosophila melanogaster* EcR DBD with liganded zinc fingers, T-box, and A box. (b) Sequence of *D. melanogaster* USP DBD with liganded zinc fingers and T-box. Lower case letters designate artifacts of cloning in the constructs used for the study. (Reproduced with permission from Devarakonda, S., Harp, J.M., Kim, Y., Ozyhar, A., Rastinejad, F., **2003**. Structure of the heterodimeric ecdysone receptor DNA-binding complex. *EMBO J. 22*, 5827–5840.)

T-box motif, which plays a role in site recognition of DNA response elements but is not essential for heterodimerization (**Figure 3**; Niedziela-Majka *et al*., 2000; Devarakonda *et al*., 2003).

3.5.2.1.4. The E domain or ligand binding domain (LBD) The domain of the nuclear receptor which is responsible for interacting with the receptor's cognate ligand is the E domain or LBD. The EcR and USP LBD fall within the canonical organization observed for almost all other members of the nuclear receptor superfamily. The region is comprised of 12 α-helices that form a ligand-binding pocket which holds the cognate ligand. The sequence of the EcR LBD is highly conserved among the insects, consistent with the widespread occurrence of the molting hormone, 20E, among the insect orders (see **Figure 4**). Nevertheless, the EcR LBD sequences from some insect orders have not been reported, and possibly important divergences among them remain unknown. For EcR, a ligand-dependent transcriptional activation function (AF2) is localized in the most carboxy-terminal helix 12, which folds over the pocket to hold the ligand molecule inside. This folding thereby creates an interactive surface with other proteins that ultimately modulates the receptor's transcriptional activity. For nuclear receptors generally, a dimerization interface lies along helices 9 and 10 (Perlmann *et al*., 1996) and ligand-independent transcriptional functions (AF1) have also been associated with various portions of the EcR LBD (Hu *et al*., 2003). Later portions of the chapter will explore not only the functional features of the LBD based on biochemical, cellular, and *in vivo* experiments, but will also discuss the effects of LBD modification and species-based sequence differences upon EcR and USP capabilities.

As noted elsewhere (see **Chapter 3.6**), the USP LBD has diverged considerably over evolutionary time. Whereas the USP LBD of some insect orders bears a fairly close resemblance to the vertebrate RXR, the dipteran and lepidopteran USP LBDs include a loop between helices 1 and 3 (**Figure 5**; Billas *et al*., 2001; Clayton *et al*., 2001). The diversity is further elaborated in the fly sequences, which include several additional, glycine-rich stretches that are not found in other insects. The aforementioned *Lm* USP includes short and long variants in the LBD which arise by an unidentified molecular process (Hayward *et al*., 2003).

Among the 21 nuclear receptors in *D. melanogaster*, all but two of these proteins (Knirps, Nauber *et al*., 1988; and Knirps-related, Oro *et al*., 1988) carry the 12 alpha-helices that typify the LBD. Except for EcR and possibly USP, none of these 19 superfamily members are known to interact physically with a cognate ligand. Several show patterns of expression that suggest a role in mediating ecdysteroid-inducible responses (Sullivan and Thummel, 2003) and one, DHR38, is activated by ecdysteroids via a novel mechanism (Baker *et al*., 2003).

3.5.2.1.5. F domain Only a few members of the nuclear receptor superfamily possess the F domain, but the EcR family members carry up to 226 amino acids (in *D. melanogaster*) beyond the helix 12 region, though these are not conserved among the insect EcR sequences. Apparently, the F-domain of *Dm*EcR is totally dispensible, since its cleavage produces a receptor that has the same transcriptional capabilities as the full-length EcR (Hu *et al*., 2003). Recently, a variant of the *Aedes albopictus* EcR has been discovered which lacks seven amino acids in this carboxy-terminal region. While the functional significance, if any, of this deviation is not known, only one of the forms normally predominates in a mosquito cell line (Jayachandran and Fallon, 2001).

3.5.2.2. Strategies for Identifying Insect Receptors

The identity of EcR described earlier by using a DNA probe derived from the E75 "early puff" gene quickly led to similar strategies for identifying EcR orthologs in other insects. These attempts have sometimes employed conventional probes, typically derived from the DBD sequence of *Dm*EcR, to screen cDNA libraries (e.g., Mouillet *et al*., 1997; Guo *et al*., 1997). In many instances a combination of approaches utilizing cDNA library screening along with polymerase chain reaction (PCR) using primers from conserved EcR regions have been utilized to obtain full-length EcR cDNA clones (e.g., Swevers *et al*., 1995). Similarly, the use of PCR to amplify a small portion of the EcR DBD sequence, followed by cDNA library searches has also resulted in the successful recovery of EcR cDNA clones (e.g., Hannan and Hill, 1997). Because many insects encode multiple EcR isoforms, 5′ and 3′ rapid amplification of cDNA ends (RACE) has been used with primers derived from regions of the EcR cDNA shared among all the isoforms. These extensions from a common region within the EcR sequence such as the DBD or LBD permit the rapid recovery of novel transcripts with isoform-specific coding regions (e.g., Minakuchi *et al*., 2002).

The recovery of the *D. melanogaster ultraspiracle* (*usp*) gene resulted from three independent screens using vertebrate RXR as a probe (Oro *et al*., 1990),

Figure 5 Continued

employing an oligonucleotide derived from a highly conserved portion of the DBD to screen an embryonic cDNA library (Henrich *et al*., 1990), and by using a promoter element in the s15 chorion gene to screen an expression library (Shea *et al*., 1990). A genomic clone residing near the tip of the *D. melanogaster* X chromosome rescues larvae homozygous for the early larval lethal mutation, *ultraspiracle* (*usp*; Oro *et al*., 1990), so named because mutant larvae fail to shed their first instar cuticle and appear to develop an extra row of spiracles (Perrimon *et al*., 1985). The same combination of PCR-based and library screening approaches used for finding EcR have led to the recovery of complete USP sequences from other insects.

The discovery that E75 was not only a target of ecdysteroid action, but a nuclear receptor itself, proved to be the first of several serendipitous discoveries of other nuclear receptors in the *Drosophila* genome that are associated directly with the salivary gland puffing response mediated by EcR and USP. Another "early late" puff gene product, E78, is a member of the nuclear receptor superfamily (Stone and Thummel, 1993) as is DHR3, which had been recovered in the same library screen that yielded EcR (Koelle *et al*., 1992); DHR3 is also a heterodimeric partner of EcR (White *et al*., 1997). Still another nuclear receptor, βFTZ-F1, a transcriptional regulator of the embryonic segmentation gene *fushi tarazu* (Lavorgna *et al*., 1991) is the product of the stage-specific 75CD chromosomal puff that occurs during the mid-prepupal ecdysteroid peak (Woodard *et al*., 1994).

More systematic screens have yielded other *Drosophila* hormone receptors (DHRs), including DHR4 (Sullivan and Thummel, 2003), DHR39 (Horner *et al*., 1995), and DHR78 (Fisk and Thummel, 1998), which are orphans and ecdysteroid-regulated. Based on USP's possible homology to RXR, a yeast two-hybrid assay employing USP as bait led to the isolation of an interacting orphan receptor, DHR38, that is orthologous to the vertebrate nerve growth factor 1B (NGF1B; Sutherland *et al*., 1995). The *seven-up* (*svp*) gene, originally defined by a mutation that disrupts photoreceptor function, encodes the *Drosophila* ortholog of another vertebrate orphan, the chicken ovalbumin upstream promoter-transcription factor (COUP-TF; Mlodzik *et al*., 1990). COUP-TF heterodimerizes with RXR, and analogously, SVP forms a functional heterodimer with USP as shown by its ability to compete for dimerization with EcR in both *D. melanogaster* (Zelhof *et al*., 1995a) and *A. aegypti* (Zhu *et al*., 2003a).

Therefore, the orphan nuclear receptors not only resemble EcR and USP structurally, it is increasingly apparent that they also play a role in the orchestration of ecdysteroid response, both as targets of EcR and USP-mediated transcriptional activity and as heterodimeric partners for the two functional components of the ecdysteroid receptor. Each of these orphans is sufficiently unique in sequence that a combination of library screening and PCR approaches have led to the successful recovery of orphan orthologs. A listing of the orphans implicated in some aspect of ecdysteroid regulation from other insect species is given in **Table 1**. Later in the chapter, the regulation and developmental roles of these orphans in *D. melanogaster* and other insects will be explored and compared further. The transcript levels of all 21 nuclear receptors found in the *D. melanogaster* genome have been analyzed preliminarily to reveal their potential connection with ecdysteroid-regulated developmental events. Some of these have not been functionally associated with ecdysteroid action and play a role in other developmental processes (Sullivan and Thummel, 2003, and references therein); these will not be considered further in this chapter.

3.5.2.3. Homology Models and Crystal Structure for Ecdysteroid Receptor Components

The need to understand the interaction of EcR with its natural ligand and other ecdysteroid agonists has prompted efforts to elucidate the crystal structure of the EcR LBD. Homology models based on a comparison of the EcR LBD with the known crystal structures of the vertebrate retinoic acid receptor (RAR) and vitamin D receptor (VDR) have been employed to formulate predictions about the three-dimensional structure of the EcR LBD (Wurtz *et al*., 2000). The docking model resulting from this comparison with known crystal structures suggests that the ligand-binding pocket of EcR consists of a shallow tube that is just large enough to accommodate 20E and a bulky envelope. The shape and size of the

pocket predicted by this model also indicate that the more compact bisacylhydrazines that behave as nonsteroidal agonists of EcR fill up only a portion of the pocket. The crystal structure of *Hv*EcR has shown that the EcR LBD is highly flexible, and that the shape of its ligand-binding pocket adapts to the ligand that occupies it, whether it be 20E, or a nonsteroidal agonist (**Figure 6**; Billas *et al.*, 2003). Just as the crystal structure predicts, substitution of an amino acid that normally contacts 20E (A398P in *Hv*EcR; see **Figure 4** for its position in other EcR sequences) destroys *Hv*EcR's ability to mediate an inducible transcriptional response to 20E, but the same mutation does not affect the inducibility caused by a nonsteroidal agonist. The crystal structure further predicts that a valine residue residing in helix 5 of Lepidoptera EcR sequences (V384 in *Hv*EcR) is responsible for the high affinity of a lepidopteran-specific agonist, BY106830. Most insect EcRs from other orders encode a methionine at this position in helix 5 (see **Figure 4**). The flexibility of the EcR LBD which allows it to bind structurally disparate ligands, presumably is stabilized by heterodimerization with USP.

When USP is purified for crystal structure analysis, a phospholipid is copurified that is partially embedded in the relatively large ligand-binding pocket of USP. As a consequence, the USP ligand-binding domain is held in an antagonistic, apo-conformation in which the carboxy-terminal region including the last alpha-helix (helix 12) is held out (**Figure 7**; Billas *et al.*, 2001; Clayton *et al.*, 2001). Another modeling study has shown that the USP LBD possesses the theoretical capability to reconfigure itself into an agonist position and interact with protein cofactors, although the residues involved in these interactions would be different from those exposed on the RXR-α homolog when it assumes an agonist conformation (Sasorith *et al.*, 2002). Modelling has also been employed to determine the capability for the three major juvenile hormones (JH1, JH2, and JH3) to bind to the ligand-binding pocket of USP. At least two ligand-binding configurations were identified, one associated with USP forms that carry an arginine residue at a critical position in helix 5 (see **Figure 5**). This residue prevails among the non-dipteran species for which the model predicted that JH acids could form a stable binding configuration.

For the dipteran species, which typically carry a nonpolar amino acid at this position in helix 5, JH esters showed better affinity than JH acids, consistent with the results of biochemical binding studies performed on the *Drosophila* USP in which a purified USP fusion protein shows half-maximal binding in the range of 1–5 μM using a tryptophan fluorescence assay (Jones *et al.*, 2001). While the modeling demonstrates the theoretical capability for various JH forms to bind to either lepidopteran or dipteran forms of USP, the occupancy rate of the ligand-binding pocket for them is relatively low for nuclear receptors. Nevertheless, other studies indicate that biological relevance does not always depend upon a high ligand binding affinity (Forman *et al.*, 1995; Kitareewan *et al.*, 1996; Staudinger *et al.*, 2001). For instance, the affinity of the vertebrate peroxisome proliferator activating receptors (PPARs) involves ligand interactions of low specificity and affinity that approximates the levels predicted for USP and JH forms (Schmidt *et al.*, 1992). Viewed from this perspective, the low affinity of a receptor for its activating ligand actually suggests a

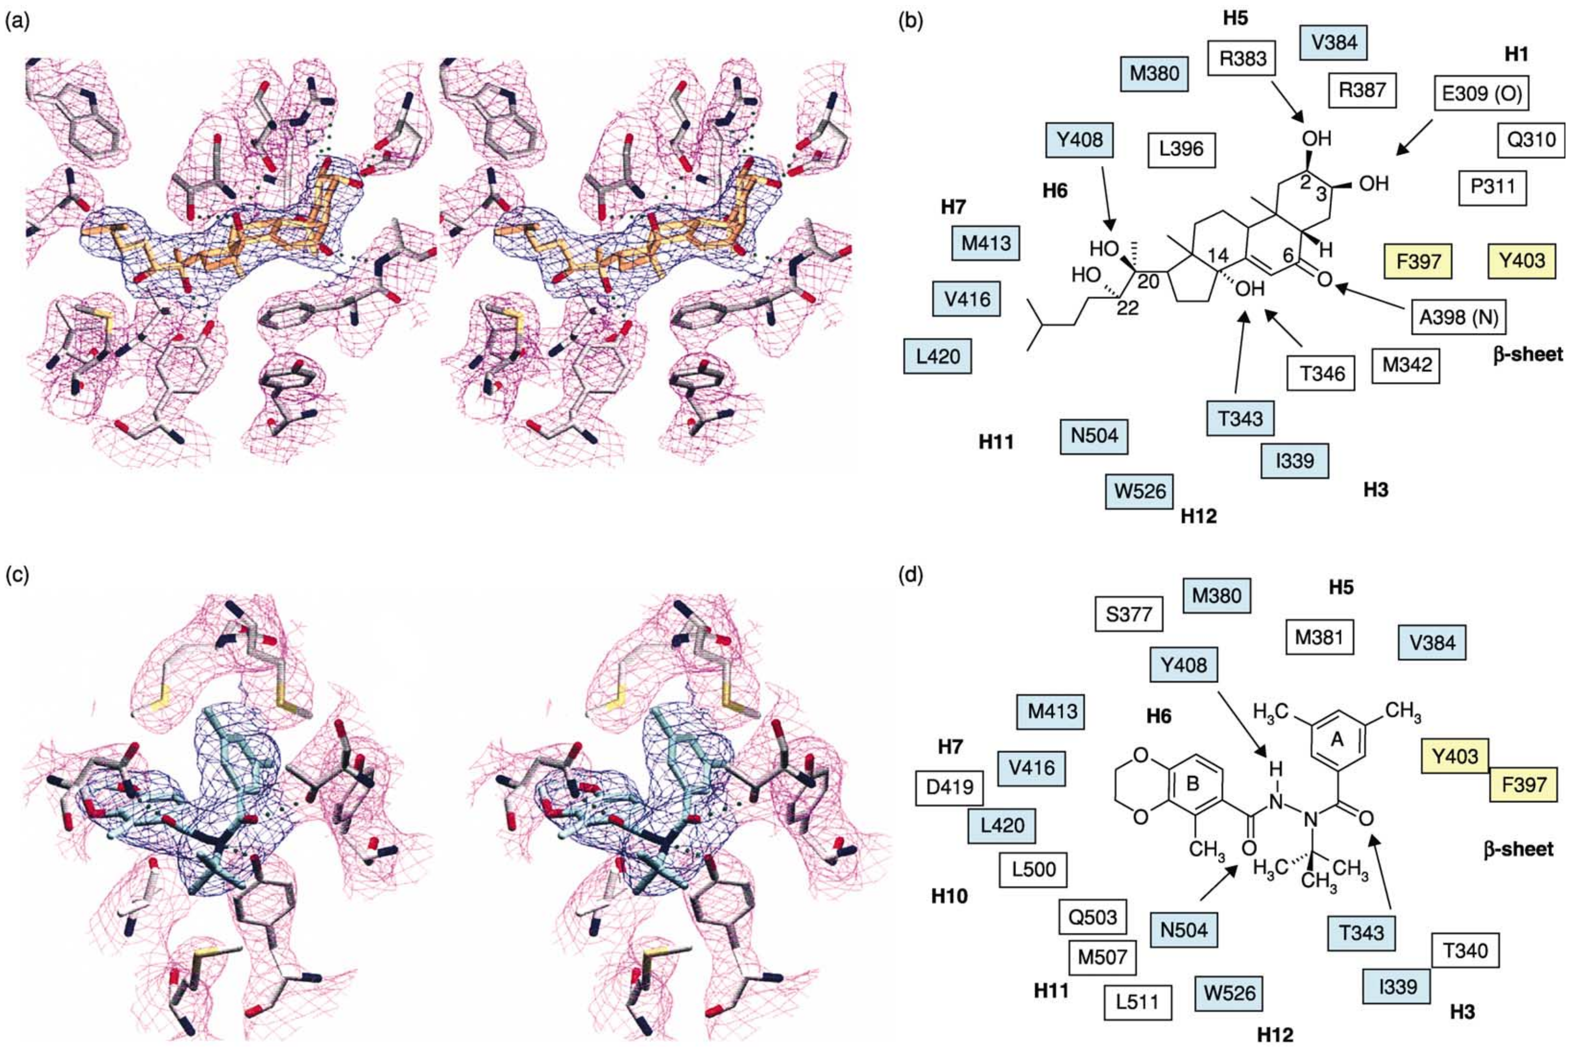

Figure 6 Two ligand binding modes for *Hv*EcR LBD as described in Billas *et al*. (2003). (a) Two weighted omit stereoview maps of the electron density for ponasterone A-bound HvEcR-LBD at 2.9 Å resolution. Ligand shown in blue and selected amino acid residues shown in magenta. Interactions between residues and ligand indicated as green dotted lines. (b) Schematic representation of the interactions between ligand-binding residues and ponasterone A. Arrows correspond to hydrogen bonds between ligand and amino acid residues. Residues in blue are common to both stereoview structures in (a), residues in white are those depicted only in the first stereoview map, and those in yellow are depicted only in the second (righthand) map. (c) two weighted stereoview maps, as above, with the nonsteroidal agonist, BYI06830. (d) schematic representation of the interactions between ligand-binding residues and BYI06830. Structure of the heterodimeric ecdysone receptor DNA-binding complex. *EMBO J. 22*, 5827–5840.)

mechanism by which fairly tight regulation is achieved when ligand titers reach relatively high levels in the cell. A discussion of functional experiments concerning the effects of JH on the ecdysteroid receptor components, EcR and USP, is presented later.

The crystal structure of the EcR and USP DBD at a canonical EcRE DNA-binding site reveals the nature and location of DNA-binding residues for the two DBD regions, as well as their points of protein-protein interaction (Figure 8). While RXR forms a functional dimer with EcR (Christopherson *et al.*, 1992; Yao *et al.*, 1993), the physical interaction between USP/RXR and EcR is different than it is for RXR with several of its natural partners (**Figure 9**; Devarakonda *et al.*, 2003).

The ability of the DHR38/USP heterodimer to induce transcription in response to ecdysteroids, even though the complex does not physically interact with its ligand, has prompted a crystal structure analysis of the DHR38 LBD. DHR38 lacks a true ligand-binding pocket – the space is filled with four phenylalanine side chains. The dimerization interface apparently lies along helix 10, but DHR38 lacks helix 12, and its AF2 function may reside in an unique sequence lying between helix 9 and 10 in an activated (agonistic) conformation (Baker *et al.*, 2003).

3.5.2.4. Biochemical Analysis of EcR and USP

Numerous biochemical experiments have been performed to assess the properties associated with EcR and USP function in insects, including: (1) the affinity of EcR for ecdysteroids and nonsteroidal agonists, (2) the ability of EcR and USP to dimerize and interact with DNA target sequences, (3) the physical interaction of EcR and USP with other orphan receptors and proteins, and (4) the detection and demonstration of posttranslational and other modified forms of EcR and USP.

The necessity for heterodimerization between EcR and USP to produce a functional ecdysteroid receptor was demonstrated by showing that the *in vitro* translated EcR and USP products bind to a radiolabelled *hsp27* EcRE, but that neither product alone is capable of binding to the same element, based on the results of an electrophoretic mobility shift assay (EMSA). Moreover, this effect is enhanced by the simultaneous presence of muristerone A or

20E, indicating that the hormone stabilizes the heterodimer at an EcRE site. Further, the affinity of radiolabelled ^{125}I-iodoponasterone, an ecdysteroid with high specific activity and affinity for EcR (Cherbas *et al.*, 1988), is substantially higher for EcR/USP dimers than for EcR alone ($\sim K_d = 1$ nM; Yao *et al.*, 1993). A similar level of ligand affinity is obtained with extracts taken from cultured *Drosophila* Kc and S2 cells, which contain endogenously expressed USP (Koelle *et al.*, 1991). EcR also heterodimerizes with the vertebrate RXR and this heterologous dimer is responsive to muristerone A, but not 20E, indicating that USP plays some role in determining the ligand specificity of the complex (Christopherson *et al.*, 1992; Yao *et al.*, 1993). The ability of EcR and USP candidates to heterodimerize on an *hsp27* EcRE has become a standard for verification (e.g., Swevers *et al.*, 1996; Hannan and Hill, 2001; Durica *et al.*, 2002; Minakuchi *et al.*, 2002).

The EcR/USP heterodimers from other insects show an affinity for ^{125}I-iodoponasterone and [^{3}H]-ponasterone A that approximates the *Dm*EcR/USP heterodimer (e.g., $K_d = 1.1$ nM; Swevers *et al.*, 1996). For *Aa*EcR and *Aa*USP, the detection of EcR/USP heterodimers in a mammalian cell culture extract increases approximately 25-fold with the addition of 5 μM 20E. This accompanies a decrease in the quantity of *Aa*USP/*Aa*SVP heterodimers, thus illustrating the competitive dynamics of these two protein–protein interactions involving USP (Zhu *et al.*, 2003a).

The ability of nonsteroidal agonists, such as the diacylhydrazines, RH5849 (1,2-dibenzoyl-1-*tert*-butylhydrazine) and RH5992 (tebufenozide), to displace radiolabelled ponasterone has been used to assess EcR specificity for these compounds. When extracts from a lepidopteran (Sf9) and dipteran insect cell line (Kc) are compared for the ability of the diacylhydrazines to displace [^{3}H]-ponasterone A, the affinity of all RH compounds is considerably lower in the Kc cells (Nakagawa *et al.*, 2002). Also, none of several RH compounds fail to displace [^{3}H]-ponasterone A in extracts containing the migratory locust's EcR and USP, indicating that the orthopteran EcR, like those of other ancient insect orders, possesses substantially different binding properties than those of the Lepidoptera (Hayward *et al.*, 2003). Ligand binding requires the entire LBD, and deletion of a portion of helix 12 at the carboxy-terminal end of EcR is sufficient to eliminate ponasterone A binding (Perera *et al.*, 1999b; Hu *et al.*, 2003; Grebe *et al.*, 2003).

Fusion proteins expressing wild-type and mutated versions of *Dm*EcR and *Dm*USP LBDs in yeast cells have also been subjected to tests of their affinity for ponasterone A in cell extracts (Grebe *et al.*, 2003). The association rate of a *Dm*EcR LBD fusion protein is modestly elevated by the presence of USP, and the dissociation rate is reduced by about 20-fold, so that the dissociation constant is reduced from about 40 nM in EcR alone to about 0.5 nM in the presence of USP. At least one mutation of the *Drosophila* EcR LBD (N626K) alters the rate of dissociation without affecting association rate, suggesting that an ecdysteroid enters and exits the EcR ligand-binding pocket by different routes, though this effect has not been tested in the intact EcR or *in vivo*. Purified *Dm*USP has the potential to form homodimers and other oligomers, even in the absence of a DNA-binding site, though this capability is reduced by removal of the A/B domain (Rymarczyk *et al.*, 2003).

Along with its ligand-binding properties, the ability to recognize a DNA element, usually the consensus *hsp27* EcRE by an EcR/USP or EcR/RXR dimer, is a standard for identifying a functional ecdysteroid receptor. The *hsp27* EcRE was originally localized by DNAse I footprinting and its ability to confer ecdysteroid-inducibility on an otherwise noninducible promoter in S1 *Drosophila* cultured cells. The sequence is 23 bp long and arranged in an inverted palindrome separated by a single nucleotide (Riddihough and Pelham, 1987). The EcR and USP zinc finger interactions with an idealized palindromic EcRE and with each other are described diagrammatically (**Figure 3**; Ozyhar and Pongs, 1993; Devarakonda *et al.*, 2003) and shown graphically (**Figure 8**). A diagrammatic depiction of the nature of individual nucleotide interactions between the element and the zinc fingers is also shown in **Figure 9** (Devarakonda *et al.*, 2003). A closely related response element taken from an ecdysteroid-inducible gene in Kc cells, Eip28/29, has also been used experimentally (Cherbas *et al.*, 1991). The EcR/USP heterodimer also recognizes half sites arranged into direct repeats (DR) separated by 0–5 nucleotide spacers (DR0–DR5) with the DR4 element showing the highest affinity. Various direct repeat elements were tested with the ecdysteroid-inducible and fat body-specific *fbp1* promoter. When these direct repeat elements are connected to the minimal *fbp1* promoter, they are unable to induce higher transcription in the presence of ecdysteroids. However, when the DR0 and DR3 elements are substituted for the natural *fbp1* EcRE in its normal promoter context, both elements are ecdysteroid-inducible and fat body specific (Antoniewski *et al.*, 1996).

Context is also important for the intermolt, *sgs4* gene promoter, which requires that an EcRE be surrounded by serum element binding protein

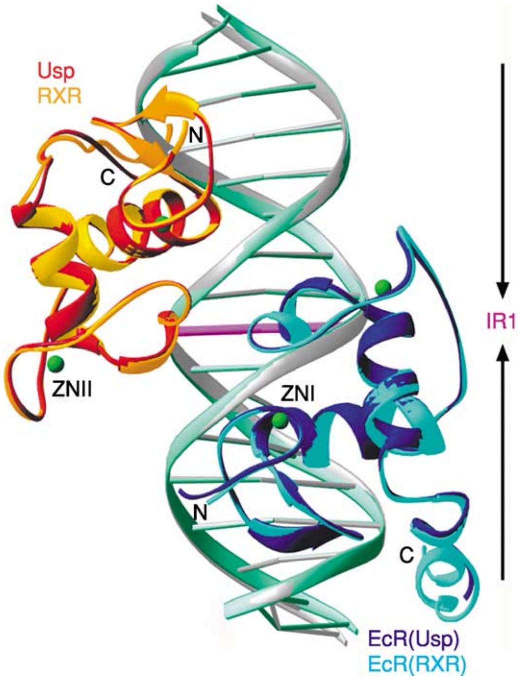

Figure 9 A superposition of the *Dm*EcR/*Dm*USP/IR1 DNA complex and the *Dm*EcR/*Hs*RXR/IR1 DNA complex. USP is shown in red, RXR is shown in gold. EcR with USP is shown in purple, and EcR with RXR is shown in light blue. Zinc ions are shown in green and the single base pair spacer nucleotide is shown as magenta. Structure of the heterodimeric ecdysone receptor DNA-binding complex. *EMBO J. 22*, 5827–5840.)

(SEBP) binding sites in order to mediate a receptor-inducible response (Lehman and Korge, 1995).

A perfect palindrome carrying the half-site sequence, GAGGTCA separated by a single A/T nucleotide (PAL1) shows the highest affinity for the *Dm*EcR/*Dm*USP complex in extracts taken from *Drosophila* S2 cells. By testing the ability of other elements to compete for this element, the order of affinity is been determined: PAL1 > DR4 > DR5 > PAL0 > DR2 > DR1 > hsp27,DR3 > DR0. In all cases, affinity is elevated by the presence of muristerone A. In cell culture experiments testing the inducibility of these elements when attached to a minimal promoter, inducibility correlates with affinity, except that the *hsp27* EcRE is a stronger inducing element than DR1, DR2, or PAL0. When DR4 is placed in a reverse orientation relative to the promoter, it maintains its ability to mediate a transcriptional response (Vogtli *et al.*, 1998). A similar correlation between DNA affinity and inducibility has been noted for the *Aa*EcR/*Aa*USP complex and its response elements (Wang *et al.*, 1998).

A natural direct repeat EcRE has been identified in the ecdysteroid-regulated intermolt 3C puff of *D. melanogaster* that is separated by 12 nucleotides (DR12) which is capable of conferring ecdysteroid-responsiveness to a heterologous promoter in cell cultures (D'Avino *et al.*, 1995). The affinity of the EcR/USP complex for the DR12 element is offset by the presence of other orphan receptors (DHR38, DHR39, *β*FTZF1), and a weak inductive response to 20E is also offset by the presence of these orphans (Crispi *et al.*, 1998). A similar competition scenario exists between *Dm*EcR and *Dm*SVP as heterodimeric partners with *Dm*USP. The SVP/USP dimer preferentially binds to a DR1 element, whereas the EcR/USP dimer displays a heightened affinity for an Eip28/29 EcRE (Zelhof *et al.*, 1995a).

The recognition of these canonical elements also depends upon specific features of the ecdysteroid receptor itself. In at least one instance, DNA recognition depends upon isoform-specific EcR and USP combinations. The EcR heterodimers formed with each of the two USP/RXR isoforms in the ixodid tick, *A. americanum,* display substantially different affinities for DNA response element sequences, with an RXR1/EcR dimer showing strong affinity for both palindromic and direct repeat sequences, whereas an RXR2/EcR dimer shows only weak affinity for a PAL1 element (Palmer *et al.*, 2002).

Ligand-binding specificity also plays a role in determining the affinity of EcR/USP for a response element. *Aa*EcR/*Dm*USP recognition of an *hsp27* EcRE on EMSAs is normally enhanced by the presence of ecdysone, but only 20E enhances affinity of the *Dm*EcR in this assay. Domain swapping between the *Aa*EcR and the *Dm*EcR localizes a region within the LBD that is responsible for the differential effect of ecdysone on the two EcRs. Within the swapped region, a single amino acid conversion in the *Dm*EcR (Y611F) to the corresponding *Aa*EcR sequence results in a mutated receptor that shows the ability to dimerize in the presence of both 20E and ecdysone (Wang *et al.*, 2000). Interestingly, all insect EcR sequences encode either a tyrosine or phenylalanine at this position in helix 10, which lies along a dimerization interface. The subtle yet significant difference in sequence, when considered in the framework of the numerous residue differences that exist among the insect EcR LBDs, illustrates the dimensions of potential functional diversity among them.

Generally, the interpretation of EMSA results must be handled circumspectively because purified EcR/USP proteins do not always exhibit the same DNA binding properties as cell extracts which include the receptor components (e.g., Lan *et al.*, 1999; Palmer *et al.*, 2002). This is exemplified in the extreme by the observation that affinity column

purified *Dm*EcR and *Dm*USP, when mixed together, fail to bind to the *hsp27* EcRE unless other chaperone proteins are added. While no single chaperone is essential for DNA binding, the elimination of any one of them proportionally reduces EcRE recognition. The formation of this chaperone/receptor complex also requires ATP, although none of these chaperones is necessary for ligand binding. Only two of the six chaperones described, Hsp90 and Hsc70, are *Drosophila* proteins; the others used in the study were human chaperone proteins (Arbeitman and Hogness, 2000).

By expressing GST fusion proteins in *E. coli* and using affinity chromatography to purify them, preparations of *Chironomus* EcR and USP have been recovered which retain essential DNA-binding and ligand-binding characteristics as long as detergents are absent from the purification process. Scatchard plots of bacterially expressed *Ct*EcR reveal two high-affinity ecdysteroid binding sites, as do extracts from a *Chironomus* epithelial cell line (Grebe *et al*., 2000). Bacterial GST-fusion proteins expressing the *Drosophila* EcR and USP DNA-binding domains have also been isolated for the purpose of testing their affinity to DNA elements, although the GST motif alters the DNA-binding properties of the fusion protein (Niedziela-Majka *et al*., 1998; Grebe and Spindler-Barth, 2002). Similarly, the recovery of a fusion protein encoding the *Dm*EcR LBD is enhanced by cleaving the C-terminal F-domain, which is considerably longer in *D. melanogaster* than other species (Halling *et al*., 1999); this cleavage exerts no discernible effect on transcriptional activity (Hu *et al*., 2003).

Since EcR and USP function as part of a protein complex, orphan receptors and cofactors described throughout the chapter typically require the discovery and/or demonstration of a physical interaction. These demonstrations include the use of yeast two-hybrid assays (e.g., Sutherland *et al*., 1995; Beckstead *et al*., 2001), the interaction of *in vitro* translated EcR and USP with a protein or protein domain (e.g., Bai *et al*., 2000), and the identification of interacting proteins that coprecipitate with EcR and/or USP (e.g., Sedkov *et al*., 2003). A member of another class of proteins, the immunophilins, which are known to interact with vertebrate steroid receptor complexes, coprecipitates as part of an EcR/USP complex taken from *M. sexta* prothoracic (ecdysteroidogenic) glands. Ligand affinity of the complex falls within an expected range, though it is unknown whether the interaction between the immunophilin, FKBP46, and EcR/USP is direct and also unknown whether this interaction affects transcriptional activity (Song *et al*., 1997).

The colocalization of proteins such as RNA polymerase II and EcR on *Chironomus* polytene chromosomes by immunostaining illustrates a possible relationship between the complex and the cell's transcriptional machinery (see **Figure 1**; Yao *et al*., 1993; Wegmann *et al*., 1995). A zinc finger protein that preferentially localizes at active puffs along *Drosophila* polytene chromosomes, known as peptide on ecdysone puffs (PEP), has been characterized by anti-PEP antibody decoration of polytene chromosomes, but has not yet been functionally associated with ecdysteroid action (Amero *et al*., 1991).

The effect of posttranslational modifications upon ecdysteroid activity has also not been explored extensively, though a phosphorylated form of *Dm*USP in fly larvae has been identified by showing that phosphatase activity eliminates a high molecular weight band in larval extracts. The phosphorylated form of USP in larval salivary glands is elevated by incubation with 20E (Song *et al*., 2003). Similarly, the presence of a phosphorylated form of both *Ct*EcR and *Ct*USP extracted from *C. tentans* larvae has been demonstrated on Western immunoblots (Rauch *et al*., 1998). The relative abundance of phosphorylated forms of the two USP isoforms in the *M. sexta* prothoracic gland is altered by the presence of 20E and has been associated with changes in ecdysteroidogenic activity, suggesting a feedback mechanism by which ecdysteroid synthesis is downregulated in prothoracic glands (Song and Gilbert, 1998).

While several groups have employed DNA cloning methods to recover receptor genes from which protein sequences are deduced, other efforts have demonstrated receptor purification through measurements of their activity. Partial purification of an ecdysteroid-binding protein from *Drosophila* embryos produces two peptides that are radiolabelled by a 20E derivative, one of 150 kDa and another of 90 kDa (Strangmann-Diekmann *et al*., 1990), the latter being the molecular weight predicted from the *Drosophila* EcR cDNA sequence (Koelle *et al*., 1991). Purification of the protein through its affinity to a magnetic *hsp27* EcRE failed to resolve the disparity between the measured size of the purified product and the predicted size of the protein (Ozyhar *et al*., 1992). Purification of the 20E receptor yielded a protein that binds to the appropriate response element sequence of the *hsp27* promoter, as well as an *hsp23* promoter element, and elevates transcription rates by 100-fold (Luo *et al*., 1991). The presence of ecdysteroids increases the affinity of the receptor protein as measured by EMSA.

3.5.3. Functional Characterization of the Ecdysteroid Receptor

3.5.3.1. Cell Culture Studies: Rationale

The study of EcR and USP *in vivo* is complicated because ecdysteroid responses vary both spatially and temporally. In fact, the effects of ecdysteroids can be obscured by the heterogeneity of response at the promoter of a single gene (Andres and Cherbas, 1992; Andres and Cherbas, 1994). Therefore, it is often difficult to unravel *in vivo* transcriptional and cellular responses mechanistically, even in a single cell type, since the response to ecdysteroids typically triggers ongoing changes in the target cell, that in turn, affect later ecdysteroid responses.

Cell cultures provide the benefit of working with a stable, relatively homogeneous cell type that does not require the rigorous staging and rearing conditions necessary for meaningful studies *in vivo*. Thus, cultured cells can provide a variety of important and useful insights about EcR and USP by establishing a foundation for subsequent *in vivo* hypothesis testing. Because they are easy to grow, it is also relatively easy to recover cellular extracts for biochemical testing. Nevertheless, stably cultured cells probably do not duplicate any actual cell exactly, so that observations reflect what a cell can do, but not necessarily what a cell does. Therefore, subsequent *in vivo* verification is essential for insights garnered through cell culture experiments.

Numerous experiments involving cultured cell lines have been conducted over the years to test the ability of the ecdysteroid receptor to regulate transcriptional activity induced by ecdysteroid treatment. Early experiments focused on endogenous changes in cell morphology and gene expression in insect cells challenged with ecdysteroids such as 20E, which express EcR and USP endogenously. As transfection technology has developed, increasingly sophisticated cell systems have been developed to analyze and dissect receptor functions. In recent years these systems have been developed to screen for novel agonists and devise "new and improved" ecdysteroid induction systems for agricultural, biomedical, and commercial application (see **Chapter 3.4**).

3.5.3.2. Cell Cultures: Characterization

The most prominent cell line for early studies of ecdysteroid action was the *D. melanogaster* Kc cell line, and derivatives of it are still employed today (Hu *et al.*, 2003). In response to 20E at 10^{-7} to 10^{-8} M, Kc cells start to develop extensions within hours, produce acetylcholinesterase, and undergo a proliferative arrest a few days later. These cells are even more responsive to the phytoecdysteroids, ponasterone A and muristerone A, than to 20E (Cherbas *et al.*, 1980 and references therein). With prolonged exposure to ecdysteroids, Kc cells become insensitive to 20E and EcR levels become depressed (Koelle *et al.*, 1991). The nonsteroidal agonist RH5849 not only mimics the effects of 20E when tested on sensitive Kc cells, it also fails to evoke a response from insensitive Kc cells, thus arguing that the RH5849 acts via a common mechanism with ecdysteroids (Wing, 1988).

Other cell lines, Schneider 2 and 3 (S2 and S3), also become insensitive to ecdysteroid action by reducing their titer of EcR, and have been used because they are relatively easy to transfect transiently with fusion and reporter genes. As noted earlier, the identity of the *Dm*EcR gene was partly demonstrated by introducing the *Dm*EcR cDNA into ecdysteroid-insensitive S2 cells and thus restoring their responsiveness to 20E (Koelle *et al.*, 1991). More recently, Kc cell lines have been improved by developing protocols for stable integration of transgenes by P-element transposition into the genome (Segal *et al.*, 1996) and by using parahomologous gene targeting to "knock out" an endogenous gene target (Cherbas and Cherbas, 1997). In this way, a cell line, L57-3-11 containing no endogenous EcR has been produced which allows the introduction of modified versions of EcR for subsequent experimentation, without the complications normally posed by the presence of endogenous EcR (Hu *et al.*, 2003).

The Kc cell line has been used to identify ecdysteroid-regulated transcriptional targets. By comparing hormone-treated and control Kc cells, Savakis *et al.* (1980) isolated and identified three ecdysteroid-inducible peptides (EIPs) named by their molecular mass in kiloDaltons, EIP28, EIP29, and EIP40, whose synthesis is elevated 10-fold at 10^{-8} M 20E. JH supplementation of the cell culture medium inhibits acetylcholinesterase induction but not EIP induction (Cherbas *et al.*, 1989).

The use of ecdysteroid-responsive lines for other insects is expanding continuously, largely in order to understand the causes of insecticidal resistance to ecdysteroid agonists and to identify novel insecticidal candidates. A *C. tentans* epithelial cell line was used to isolate several stable and ecdysteroid-resistant clones that metabolizes 20E relatively quickly (Spindler-Barth and Spindler, 1998). Clones from the same line were later selected for their resistance to the inductive effects of RH5992 and differential metabolism of RH5992 was ruled out as a cause for the resistance. While the profile of EcR in these cells is approximately normal, some

lines shows a modest decline in the abundance of phosphorylated USP forms that is not reversible by addition of 20E. A variety of differences in EcR ligand-binding characteristics were noted among the cell lines tested that presumably reflect the role of unknown factors underlying the resistance (Grebe *et al*., 2000).

Another widely used lepidopteran cell line is Sf9, derived from ovarian cells of the fall armyworm, *Spodoptera frugiperda*. The affinity of ponasterone A for Sf9 and Kc cells is very similar, but the nonsteroidal agonist ANS-118 (chromafenozide) displays a much higher affinity for extracts derived from Sf9 cells than from Kc cells (Toya *et al*., 2002). Similarly, cell lines derived from *C. fumeriferana* show a much greater responsiveness to RH5992 than *Drosophila* cultured cells, which do not respond to the compound and excrete it an elevated rate via an ABC transporter system (Retnakaran *et al*., 2001). *Choristoneura* cell lines, with prolonged exposure to RH5992 become irreversibly insensitive to ecdysteroids and to the agonist, though the mechanism is unknown (Hu *et al*., 2004). A more comprehensive discussion of ecdysteroid agonist properties is provided elsewhere in this series (see **Chapter 3.4**), though it is clear that the differences among species are derived primarily from structural diversifications in EcR and possibly, USP (see **Chapter 3.6**).

Other lines are particularly useful for studying ecdysteroid action in economically important insect species even when a complete EcR and USP have not been yet been isolated. These lines include the European corn borer (*Ostrinia nubilalis*; Trisyono *et al*., 2000), the tent caterpillar (*Malacosoma disstria*; Palli *et al*., 1995), the fall armyworm (*Spodoptera frugiperda*; Chen *et al*., 2002a), and the cotton boll weevil (*Anthonomus grandis*; Dhadialla and Tzertzinis, 1997). The ecdysteroid responsiveness has been established for at least some of these lines by showing that orthologs for ecdysteroid responsive *D. melanogaster* genes, notably the genes encoding E75 (early puff) and DHR3 (early-late puff), are activated transcriptionally when the cells are challenged with 20E or an agonist.

A major benefit of using insect cell lines is that they provide the cofactors and machinery that are necessary for transcription to occur. On the other hand, other factors may modify or obscure an aspect of ecdysteroid response in a given experimental regime as silent and unidentified participants. As is evident from *in vivo* studies, a given experiment will generate substantially different cellular responses depending upon the milieu of proteins that contribute to ecdysteroid responsiveness in a given cell type. For this reason, mammalian cell lines containing no endogenous ecdysteroid responsiveness have been used to reconstruct an ecdysteroid responsive transcriptional system by introducing the genes encoding EcR, USP, cofactors, and reporter genes in order to analyze their individual effects on ecdysteroid action (e.g., Christopherson *et al*., 1992; Yao *et al*., 1993; Palli *et al*., 2003; Henrich *et al*., 2003). Heterologous cells and cell lines also pose special difficulties, since it is conceivable that endogenous proteins provide novel functions or act as surrogates for similar insect proteins. Conversely, these cells might render false negative results in some experiments because they are missing one or more crucial cofactors.

3.5.3.3. Cell Cultures: Functional Receptor Studies

A variety of studies have examined the capability of EcR and USP to function in insect and other cell lines. Using the same approach, several orphan receptors from *D. melanogaster* have also been tested for their ability to respond to candidate ligands. These studies have generally focused on: (1) the responsiveness and activity of target DNA sequences in promoters, (2) the effect of various ecdysteroids, agonists, and antagonists upon receptor activity, (3) the properties of specific domains on receptor function and the effect of structural modifications upon transcriptional activity, and (4) the effect of heterodimerization and other cofactors, including orphan receptors, upon transcriptional activity.

3.5.3.3.1. Promoter studies The *hsp27* EcRE connected to a weak constitutive promoter is capable of inducing the transcription of a reporter gene in a *Drosophila* cell line by over 100-fold when challenged with 20E (Riddihough and Pelham, 1987). When *hsp27* EcREs are organized in a tandem repeat and attached to a weak promoter, the gene is not only responsive to 20E, but also is repressed in the absence of hormone, suggesting a repressive role for the ecdysteroid receptor via this element (Dobens *et al*., 1991). A plethora of cell culture transcriptional tests and accompanying EMSAs have been reported which followed from this early work, and this is an important criterion for determining the functionality of an EcR/USP heterodimer, as it was in the original report (Koelle *et al*., 1991).

The most fundamental task concerning promoter activity is to define the functional promoter elements to which the ecdysteroid receptor complex binds and exerts its effects on transcription. This was accomplished for the genes encoding the aforementioned EIP28 and 29, which are translated from

alternatively spliced mRNAs of the same gene (Schulz *et al.*, 1986). Three specific ecdysone response elements are ecdysteroid-responsive *in vivo* (Andres *et al.*, 1992; Andres and Cherbas, 1994). One of these Eip28/29 EcREs lies in the promoter region though it is not required for ecdysteroid-inducibility in Kc cells, possibly because this element is not used in the embryonic hemocytes from which the cells are derived. The other two elements lie downstream from the polyadenylation site, that is, on the 3′ side of the gene (Cherbas *et al.*, 1991). The EIP40 gene is also ecdysteroid-inducible *in vivo* (Andres and Cherbas, 1992) and the genomic region that includes the EIP40 gene has been analyzed (Rebers, 1999). Just as cell culture experiments have been used to identify EcREs *in vitro* for subsequent *in vivo* analysis, the reverse relationship has also been undertaken successfully – the ecdysteroid-responsive promoter elements in the β3 tubulin gene, which is ecdysteroid-responsive *in vivo* (Sobrier *et al.*, 1989), were identified by testing their inducibility by 20E in Kc cells (Bruhat *et al.*, 1993).

Cell culture experiments have been used not only to dissect the functional ecdysteroid response elements within a promoter region, but also to examine the possibility that different factors compete for these sites to modulate transcriptional activity. The relationship of *M. sexta* EcRB1 and two *Ms*USP isoforms has been explored in *M. sexta* GV1 cell cultures by observing the ecdysteroid-inducible MHR3 promoter (Lan *et al.*, 1997). Both EcR/USP complexes display about the same level of ligand affinity, but the EcRB1/USP1 complex induces much higher levels of expression in response to 20E from an intact promoter and also represses basal expression in the absence of 20E. Further, the EcRB1/USP1 complex binds to a canonical EcRE in the promoter and activates transcription, but the addition of USP2 prevents transcription and blocks binding to the EcRE. *In vitro* translated EcRB1/USP2 can bind to this same EcRE, indicating that other cellular cofactors are responsible for the differential action of the two *Ms*USP isoforms (Lan *et al.*, 1999).

The two isoforms of *Ct*USP show somewhat different ligand-binding capabilities, and one of the forms, when purified, recognizes a DR1 element that is not recognized by the other. However, both show about the same ability to induce transcription with DmEcR in human HeLa cells. The CtEcR does not possess the ability to induce transcription in cell cultures (Vogtli *et al.*, 1999).

3.5.3.3.2. Transactivation studies The appearance of multiple EcR isoforms in *D. melanogaster* has prompted comparisons of their transcriptional responsiveness in cell cultures and in yeast. The B1 and B2 N-terminal domains from *Dm*EcR, when combined with a GAL4 DBD and and transfected into yeast, are capable of mediating transcription via a GAL4-responsive universal activation site (UAS) in the promoter. This AF1 (ligand-independent) transcriptional function is further elevated by removing an inhibitory region within the B1 domain (Mouillet *et al.*, 2001). In human HeLa cells, *Dm*EcRB1 and *Dm*EcRB2 showed about the same level of AF1 function and both also possessed AF2 (ligand-dependent) transcriptional activity. By contrast, EcRA reduced basal transcriptional activity below the level obtained from an EcR with no A/B domain at all.

Similar results have been obtained in a mammalian Chinese hamster ovary (CHO) line, except that the B1 isoform displays a highly elevated AF1 function compared to the A and B2 isoforms (Henrich *et al.*, 2003). This activity difference measured for B1 in the two cell lines suggests that the HeLa cell line carries a repressor that interacts with the B1 domain which does not exist in CHO cells. It also illustrates the diversity of function that is possible among different cell types owing to differences in the cellular milieu. In the EcR-deficient L57-3-11 line, all three EcR isoforms are responsive to ecdysteroids, though the A domain contributes no AF1 function, nor does the *Dm*USP A/B domain. The B1 domain contains several regions that when deleted impose a modest impact on AF1 functions. By contrast, specific point mutations in the B2 domain dramatically reduce AF1 functions (Hu *et al.*, 2003), suggesting that a localized interaction with other transcriptional factors is essential for activity.

Lezzi *et al.* (2002) devised a yeast two-hybrid assay which fused the EcR and USP LBD to the yeast GAL4 activation domain and DNA-binding domain, respectively. A variety of site-directed mutations of the LBDs were used to test their effects on functional dimer formation and both AF1 and AF2 (ligand-dependent) transcriptional activity as measured by UAS-mediated lacZ activity. The wild-type LBDs dimerize and induce activity at a low rate even in the absence of muristerone A, and this rate increases more than tenfold in the presence of muristerone A (but not other ecdysteroids such as 20E). Mutations of critical residues in EcR's helix 10 all but eliminate both dimerization and transcriptional activity, as expected. Deletion or mutation of helix 12, which normally folds over the ligand-filled pocket, eliminates EcR's AF2 function, as do mutations that affect ligand binding, but AF1 function is still detected in these mutant forms of

EcR. Substitution at a consensus cofactor-interacting residue, K497E, results in a strong elevation of basal transcriptional activity, though this mutant EcR has a reduced capacity for ligand-dependent induction and low ligand affinity (Bergman *et al.*, 2004; Grebe *et al.*, 2003). Virtually all point mutations in the *Dm*USP LBD eliminate transcriptional activity, though many retain the capability to dimerize with EcR, suggesting that USP is required for normal AF1 activity. Deletion of the carboxy-terminal region of *Dm*USP, including helix 12, does not disrupt homodimerization detected by gel filtration, but eliminates ligand-binding. Substitutions of specific residues in helix 12 modestly reduce basal transcriptional activity in yeast. However, while ligand-binding for the mutant USP is only slightly reduced, the ligand-dependent transcription of the EcR/USP complex is virtually eliminated (Przibilla *et al.*, 2004). This result is counterintuitive since the crystallized *Dm*USP is locked into an antagonistic conformation which implies that AF2 activity is impossible. It also contrasts with the normal activity seen in several helix 12 mutations of USP that were tested in the *Drosophila* L57-3-11 cell line, which may express enough *Dm*USP to mask the mutational effects (Hu *et al.*, 2003).

3.5.3.3.3. Ligand effects At least three issues pertaining to ligand responsiveness of the ecdysteroid receptor have been addressed through the use of cell cultures. First, one has focused on the responsiveness of a given receptor to ecdysteroids and agonists, particularly novel compounds. Second, modified receptors have been tested for their capacity to respond to a given ligand or to assess the structural basis of ligand specificity. Finally, recent studies have focused on the possibility that other orphan receptors are responsive to ecdysteroids and/or other ligands.

By testing ecdysteroid-induced transcriptional activity in cell culture, new nonsteroidal agonists, including both artificial compounds (Mikitani, 1996) and a variety of phytochemicals which act as agonists, including 8-O-acetylharpagide (Elbrecht *et al.*, 1996) or antagonists, including several flavones (Oberdorster *et al.*, 2001). Environmental chemicals including polyaromatic hydrocarbons (PAHs) and polychorinated biphenyls (PCBs) induce ecdysteroid-responsive genes, suggesting an EcR-mediated basis for molting defects commonly found among aquatic species residing in polluted water (Oberdorster *et al.*, 1999). The use of cell culture assays has also been utilized to analyze the effects of juvenile hormone and its analogs upon transcriptional activity. The topic of juvenile hormone and its effects upon EcR and USP will be addressed later in the chapter.

Based on lines of evidence gleaned from experimental studies over the years, the possibility that ecdysteroids other than 20E display biological activity has been speculated about and even suspected for years (Somme-Martin *et al.*, 1990; Grau and Lafont, 1994; Henrich and Brown, 1995). In S2 cells, the 20-hydroxylated derivates of the major and natural ecdysteroid products of the *D. melanogaster* larval ring gland, 20E and makisterone A are the most efficacious in activating a reporter gene whose promoter carried three tandem copies of the *hsp27* EcRE. By contrast, precursor and metabolite ecdysteroids, as well as nonsteroidal agonists, evoke considerably less activity in the cell culture assay. As noted in other studies, ponasterone A displays the highest potency, and two other phytoecdysteroids, muristerone A and cyasterone, also are more inducible than 20E in these cells (Baker *et al.*, 2000).

Receptor modifications have also been utilized to delineate the basis for differences in ligand specificity, as noted earlier for the effects of the A398P mutation to test predictions based on the *Hv*EcR crystal structure (Billas *et al.*, 2003). Similarly, a substitution in the *Cf*EcR (A393P) eliminates both its ligand-binding affinity for ponasterone A and its transcriptional inducibility in cell cultures, possibly by impairing the receptor's interaction with a coactivator (GRIP1), but the mutation exerts no debilitative effect on responsiveness to a nonsteroidal agonist (Kumar *et al.*, 2002). A chimeric *Drosophila/Bombyx* EcR carrying only the *Bombyx* D-domain is responsive to RH5992 in mammalian CV-1 cells. The effect is largely attributable to the relatively high level of RH5992-dependent dimerization between the D-domain of the chimera and endogenous RXR or cotransfected USP (Suhr *et al.*, 1998). Based on a deletion analysis of EcR, both its D and E domain are required for ligand-dependent dimerization with USP (Perera *et al.*, 1999b).

As already noted, insect cells may provide endogenous components that influence ecdysteroid activity. EcR itself masks a second ecdysteroid responsive activity in *Drosophila* S2 cells. A fusion protein carrying the DHR38 LBD was tested for its ability to dimerize with *Dm*USP in response to several ecdysteroids using S2 cells from which endogenous EcR activity was eliminated by RNA interference. A response to 20E occurs that is further induced by adding an RXR activator, indicating that the DHR38/RXR heterodimer is responsible for the effect. Similarly, cotransfection with a chimeric and constitutively active form of USP also confers the ability of DHR38 to respond to 20E (Baker *et al.*, 2003). The DHR38/USP dimer also responds to at least six other ecdysteroids, including some, such as

3-dehydro-20E and 3-dehydromakisterone A, which are abundant during late larval development in *Drosophila* and display unusually high inducibility in fat body (Somme-Martin *et al.*, 1990). The relevance of this pathway for ecdysteroid-driven events represents an important avenue for investigation in *Drosophila* and other insects.

Cell culture experiments have also been used to demonstrate the effect of orphan receptors and receptor cofactors upon ecdysteroid response, including AHR38 (Zhu *et al.*, 2000), *Aa*SVP (Zhu *et al.*, 2003a), *Dm*SVP (Zelhof *et al.*, 1995a), and DHR78 (Zelhof *et al.*, 1995b). These will be discussed in connection with their biological relevance for modulating ecdysteroid receptor-mediated activities.

3.5.3.4. Ecdysteroid-Inducible Cell Systems

The use of ecdysteroid-inducible cellular systems has emerged rapidly in recent years since ecdysteroids and nonsteroidal agonists are inexpensive and harmless to humans. Yeast assays have been developed to screen for ecdysteroid agonists of potential commercial value. When EcR by itself is transformed into yeast cells, it is capable of inducing a high level of transcription that is ligand-independent and which is not appreciably increased by the presence of USP or RXR (De la Cruz and Mak, 1997). Through modifications of the A/B domain, an inducible system was successfully produced (De la Cruz *et al.*, 2000).

A second ecdysteroid-inducible yeast system was produced by making at least two modifications. First, by removing the *Aa*EcR A/B domain, the receptor's AF1 function is reduced when transformed into yeast. Second, the addition of the mammalian receptor coactivator GRIP1 confers yeast cells with the ability to be induced more strongly by a range of ecdysteroid agonists. Conversely, the addition of the receptor corepressor SMRT represses transcription (Tran *et al.*, 2001a). A yeast inducible assay utilizing the *Cf*EcR and *Cf*USP also requires the removal of the A/B domain from both EcR and USP, along with the addition of the GRIP1 coactivator (Tran *et al.*, 2001b). In fact, the USP A/B domain often displays repressive properties or is inactive in heterologous cells, thus necessitating its deletion and/or replacement with a constitutively active N-terminal domain, such as VP16 (Tran *et al.*, 2001b; Hu *et al.*, 2003; Henrich *et al.*, 2003).

The field use of the bisacylhydrazines as insecticides has also inspired the introduction of ecdysteroid-inducible systems into plants which could be used to promote the expression of beneficial genes. Nonsteroidal agonist-inducible expression has been obtained from *Zea mays* (corn) protoplasts (Martinez *et al.*, 1999b), tobacco, and *Arabidopsis* (Padidam *et al.*, 2003) via EcR fusion proteins. This induction in *Arabidopsis* has been successfully linked to the expression of a coat protein gene from the tobacco mosaic virus (TMV), which confers resistance to TMV infection (Koo *et al.*, 2004) and also induces the expression of a factor in maize that restores fertility to a male-sterile strain (Unger *et al.*, 2002).

As noted, ecdysteroids evoke no discernible responses upon mammalian cells, and therefore, attempts to implant an ecdysteroid-inducible gene expression system into cells for therapeutical purposes has been undertaken. EcR dimerizes with endogenously expressed RXR to form a functional heterodimer that responds to biologically inert ecdysteroids or nonsteroidal agonists (Christopherson *et al.*, 1992; Palli *et al.*, 2003). By producing and testing a variety of chimeras, a heterologous receptor system has been developed in mammalian cells that evokes induction rates of almost 9000-fold, with very rapid reduction when the ecdysteroid agonist is removed (Palli *et al.*, 2003). A mouse strain carrying a transgenically introduced *Drosophila* EcR gene has been produced in which tissues are capable of responding to ecdysteroids without any other discernible phenotypes other than the expression of an *hsp27* EcRE regulated reporter gene (No *et al.*, 1996). The ecdysone switch has been shown to be responsive to several ecdysteroids and ecdysteroid agonists, and the maximal response can be further elevated by the addition of RXR activators. RXR superinduction requires that EcR be previously bound by its cognate ligand since RXR activators by themselves exert no effect upon EcR/RXR activity (Saez *et al.*, 2000). Ecdysteroid-inducible expression of medically important genes has been accomplished in human cell lines (Choi *et al.*, 2000), as well as the introduction of an ecdysteroid-inducible gene into rats via an adenovirus vector used for somatic gene therapy (Hoppe *et al.*, 2000).

3.5.4. Cellular, Developmental, and Genetic Analysis

3.5.4.1. The Salivary Gland Hierarchy: A Model for Steroid Hormone Action

Many of the insights concerning steroid hormone regulation of transcriptional activity were first recognized in the larval salivary gland of several insect species. By observing the location, timing, and size of these chromosomal puffs, the activity of an ecdysteroid-inducible gene can be inferred. The progression of events, and their relation to

developmental changes in the salivary gland and the whole animal are described here for *D. melanogaster* (see Thummel, 2002 and references therein). During the period of the third instar that precedes the wandering stage, "intermolt puffs" appear at several specific chromosomal sites. In response to the late larval ecdysteroid peak, these puffs regress and another set of "early" ecdysteroid-responsive puffs appear. The timing and duration of these "early" puffs varies (some are referred to as "early-late" puffs) and these eventually regress as another set of "late puffs" appear at other chromosomal sites. The puffing pattern accompanies the production and secretion of glue protein from the salivary gland, which is extruded as the larva becomes immobile and tanning of the larval cuticle begins (puparium formation).

Several hours later, a second smaller pulse of ecdysteroid induces a second wave of "early" puff activity, which is followed by a second wave of "late" puff activity. The two peaks evoke similar, but not identical, transcriptional changes, and these subtle differences underlie important developmental consequences. The second wave culminates in the expression of βFTZ-F1, a specific isoform of an orphan receptor encoded by the stage-specific (that is, the prepupal specific) gene puff located at the chromosomal interval, 75C. βFTZ-F1, in turn, sets off a cascade that ultimately includes the expression of another stage-specific puff, E93, involved in the histolysis of the gland (Broadus *et al*., 1999; Lee *et al*., 2002).

As expected, 20E shows the greatest potency in terms of puff induction, followed by 3-dehydro-20E, which is an endogenously produced ecdysteroid in the *Drosophila* third instar (Somme-Martin *et al*., 1988). Significantly, however, while the potency of individual ecdysteroids varies, no individual ecdysteroid evokes an unique puffing site, or alternatively, fails to evoke puffing at a site induced by other ecdysteroids. In other words, there is no evidence for multiple ecdysteroid signaling pathways in the *Drosophila* salivary gland (Richards, 1976).

3.5.4.2. Molecular and Genetic Characterization of the Puff Hierarchy

Numerous genetic and molecular studies have verified the basic tenets of the Ashburner model. Ashburner proposed that the ecdysteroid receptor directly induces the early puffs while simultaneously repressing late puff genes, and that the early puff gene products not only increase late puff transcription, but also feed back to downregulate their own expression. The use of chromosomal deletions and duplications of the region that contains E74 and E75 provides a way to alter the intracellular dosage of early puff gene products and thereby test the model. Late puffs appear earlier and are larger when the early puff genes are duplicated, consistent with the accumulation of an activating factor. On the other hand, late puff appearance is delayed in chromosomes with early puff deletions (Walker and Ashburner, 1981).

Further evidence that late puffing events are dependent upon early puffing events was shown ingeniously by testing permeabilized salivary glands 20E in combination with cellular extracts (Myohara and Okada, 1987). When ecdysteroid and a cellular extract from unstimulated salivary glands are mixed together, no response is registered from the late puff at 78C, but this puff appears when 20E, along with a cellular extract from stimulated salivary glands, is tested on permeabilized salivary glands.

Another line of inquiry has focused on demonstrating that EcR and USP interact directly with puff site regions. Immunostaining has shown specific instances in which EcR and USP colocalize to early puff sites (Yao *et al*., 1993), and that EcR and RNA polymerase II antibodies colocalize on *C. tentans* polytene chromosomes (see **Figure 1**). EcR has also been associated with late puff sites (Talbot *et al*., 1993), inferring that it directly influences the regulation of late puff genes. Further, the products of the early puff gene, E75, have been associated by immunostaining with early and late puff sites, as predicted by the Ashburner model (Hill *et al*., 1993).

The puff hierarchy actually begins before the onset of pupariation in *Drosophila* with the appearance of several intermolt puffs (see Lehman, 1995 and references therein). The *sgs4* gene encodes a salivary glue protein and is regulated by the synergistic interplay of an ecdysone receptor element, and a secretion enhancer binding protein (SEBP3) site. A second SEBP binding site has been associated with products of the early puff product, Broad, indicating that the proper regulatory interplay between the ecdysone receptor and other transcriptional factors depends upon the cellular milieu (von Kalm *et al*., 1994; Lehman and Korge, 1995). As ecdysteroid titers increase, the intermolt puffs regress.

Three early puff genes have been the subject of intensive ongoing study in *D. melanogaster* and other insects. All three genes encode transcription factors, consistent with a role in regulating late puff expression: the Broad-Complex (Br-C) encodes a zinc finger protein (DiBello *et al*., 1991), E74 is an *ets* protooncogene (Burtis *et al*., 1990), and E75 encodes an orphan receptor (Segraves and Hogness, 1990). All three possess a level of organizational

complexity that is not evident from the cytological studies alone. Br-C encodes several different isoforms derived from alternative splicing (DiBello *et al.*, 1991). Broad proteins carry a common core domain and a subset of several different variable domains (see Bayer *et al.*, 1997), and the expression of each isoform varies both spatially and temporally (e.g., Huet *et al.*, 1993; Mugat *et al.*, 2000; Brennan *et al.*, 2001; Riddiford *et al.*, 2003). The switchover of expression among combinations of Br-C isoforms has been associated with the modulatory regulation of many ecdysteroid-inducible genes including the transcription factor gene *hedgehog* (*hh*; Brennan *et al.*, 1998), micro-RNA (Sempere *et al.*, 2003), and *fbp1* (Mugat *et al.*, 2000). The E74 puff encodes two isoforms, one of which is transcribed at low ecdysteroid levels (E74B; Karim and Thummel, 1991) and disappears as titers become elevated while the transcript which specifies the E74A isoform becomes more abundant. Finally, three isoforms exist for the nuclear receptor at the E75 puff (A, B, and C; Segraves and Hogness, 1990) resulting from alternative splicing. One of these, E75B, carries only the second zinc finger within its DBD. Several other ecdysteroid responsive puff genes have also been identified which play cellular roles (see Thummel 2002, and references therein).

3.5.4.3. Developmental Regulation of Ecdysteroid Response in *D. melanogaster*

Transcript levels of EcR, the intermolt genes, and the individual isoforms of the early puff genes (BR-C, E74, E75) vary temporally among individual tissues during the late larval/prepupal period in *D. melanogaster* (Huet *et al.*, 1993). It is apparent that the relative abundance of the early puff isoforms changes continuously as ecdysteroid titers surge and decline, that the profile of "early puff" expression varies among tissues at any given time, and that the pattern changes are specific for a given tissue. For instance, EcR levels are very low throughout the larval/prepupal period in imaginal discs, whereas they remain elevated in the gut throughout this period. The relative abundance of EcR and its early puff products plays some role in the timing of subsequent gene expression, as exemplified by the Ddc (dopa decarboxylase) gene. It behaves as an "early late" gene and is induced by the combined action of EcR and Br-C, which is offset, in turn, by a repressive promoter element in epidermis and imaginal discs (Chen *et al.*, 2002b). A similar mechanism has been described for the suppression of Ddc in *M. sexta* (Hiruma *et al.*, 1995).

The complexity of *in vivo* response to ecdysteroids is also revealed by comparing the puffing response seen along the polytene chromosomes of the larval fat body during the same time that the salivary gland puff response occurs (Richards, 1982). While many aspects of the fat body response resemble those seen in the salivary gland, individual fat body puff sites are responsive to both ecdysone and 20E in ranges below 10^{-6} M, whereas salivary gland puffing is much more responsive to 20E. While one obvious explanation lies with differences in metabolism (see **Chapter 3.3**), the fat body response to ecdysone does not lag the response to 20E in the fat body, as would be expected if conversion to 20E preceded receptor-mediated response. Fat body chromosomes also evoke different puffing patterns than salivary gland chromosomes, and these presumably reflect functional differences between the two compared cell types.

Diversity of response has been seen for other ecdysteroid-inducible genes. For instance, the fat body protein-1 (*fbp1*) gene is ecdysteroid-inducible and expressed only in the fat body during the onset of metamorphosis (Maschat *et al.*, 1991). The aforementioned Eip28/29 gene is ecdysteroid-responsive but displays several different patterns of expression in individual tissues at the onset of metamorphosis (Andres and Cherbas, 1992, 1994). The complexity of *in vivo* regulation is also exemplified by the E93 gene, which falls at an endpoint in the salivary gland hierarchy because the E93 gene product plays a central role in salivary gland histolysis (Lee *et al.*, 2002). Nevertheless, its expression in other tissues is not responsive to 20E (Baehrecke and Thummel, 1995).

The *D. melanogaster* imaginal discs and ring gland are notable in that they apparently fail to respond to ecdysteroids during the larval/prepupal period, as measured with a GAL4-EcR/GAL4-USP *in vivo* system in which lacZ staining reports the level of ligand-dependent heterodimerization between the two fusion proteins (Kozlova and Thummel, 2002). The lack of responsiveness may reflect the effect of cofactors (or their absence) and/or mechanisms by which 20E is either removed from the cells via a transporter mechanisms (Hock *et al.*, 2000) or metabolized.

The same GAL4 *in vivo* reporter system indicates that EcR and USP heterodimerization occurs in response to the ecdysteroid peak during *D. melanogaster* mid-embryogenesis and that the receptor plays a role in germ band retraction and head involution (Kozlova and Thummel, 2003a). Moreover, the transcriptional relationship among ecdysteroid-regulated genes is generally maintained during the course of individual ecdysteroid peaks throughout premetamorphic development (Sullivan and

Thummel, 2003). Mutations of the early-late gene, DHR3, cause embryonic lethality, further implicating not only EcR but the ecdysteroid hierarchy itself (Carney *et al.*, 1997).

Of course, the existence of functionally distinct EcR isoforms provides an important basis for differential ecdysteroid responses. During the late larval stage, the EcRA isoform of *D. melanogaster* is generally predominant in imaginal discs, whereas the B isoforms are associated primarily with larval tissues that undergo histolysis during metamorphosis (Talbot *et al.*, 1993). Issues surrounding the diversity of isoform function will be discussed further in Section 3.5.4.5.

3.5.4.4. Conservation of Ecdysteroid Response Among Insects

The isolation of EcR and USP from other insects and the assembly of their developmental profiles now allows direct analysis of ecdysteroid action in other organisms. So far, these studies show general consistency with those obtained in *D. melanogaster*, specifically, EcR expression varies over time and peak levels of expression coincide with ecdysteroid peaks, and different isoforms predominate among different tissues. For instance, the expression patterns of the two EcR isoforms in *M. sexta* vary among cell types (Jindra *et al.*, 1996) and expression levels of the two USP isoforms switch in conjunction with molts (Jindra *et al.*, 1997), providing a regulatory framework for the early-late response of MHR3 discussed earlier (Lan *et al.*, 1999).

The recovery of ecdysteroid-inducible target genes such as E74, E75, FTZF1, and HR3 orthologs also allows a comparison of the ecdysteroid-inducible cascade in other organisms, and the resulting proteins play biological roles in a variety of regulatory processes that is too extensive to discuss here. The comparative analysis over preadult development is most complete in *M. sexta*, and the essential features of the ecdysteroid-inducible hierarchy are maintained (Riddiford *et al.*, 2003, and references therein). Similarly, the players and timing of ecdysteroid-responsive genes during *B. mori* choriogenesis are conserved (Swevers and Iatrou, 2003), as they are in *A. aegypti* vitellogenesis (Zhu *et al.*, 2003a) (see **Chapter 3.9**). Interestingly, however, USP's other partners, DHR38 and SVP, have not been associated with whole body responses in any organism. In flies, SVP is involved in eye differentiation (Mlodzik *et al.*, 1990) and DHR38 is involved in cuticle formation (Fisk and Thummel, 1998) at the onset of metamorphosis; both players are involved in mosquito vitellogenesis (Zhu *et al.*, 2003a) (see **Chapter 3.9**).

At least two points emerge from these considerations. First, while the early response at the core of the ecdysteroid hierarchy appears to be highly conserved among insects at the global level, local ecdysteroid responses likely recruit specific players to mediate specific developmental events. Second, combinations of the EcR/SVP/DHR38/USP orphan receptor group might be incorporated into various ecdysteroid-regulated processes for the purpose of regulating a linear series of events such as mosquito vitellogenesis and fly eye differentiation. One intriguing aspect of this orphan group is that the broad spectrum response of DHR38/USP might be important for regulating responses via the ecdysone precursor to 20E and via 20E metabolites occurring after 20E exerts its effects, with SVP providing activation of an alternative pathway by competing with the 20E-inducible response itself. The context of EcR action will be interesting to explore in other insect processes, such as the color pattern formation of butterfly wings (Koch *et al.*, 2003) and insect diapause (see **Chapter 3.12**).

Historically, numerous studies of puffing on polytene chromosomes preceded and have continued along with the work on *D. melanogaster*. The salivary gland response of *Sciara coprophila* (fungal fly) provides an interesting comparison to *D. melanogaster*, and illustrates the importance of investigating the features of each system without pretense. The *S. coprophila* II/9A puff appearing in response to ecdysteroid treatment reflects the initiation of both bi-directional DNA replication (Liang *et al.*, 1993) and the elevated transcription of two similar mRNA species which bear no resemblance to ecdysteroid-responsive genes found in *Drosophila* (DiBartolomeis and Gerbi, 1989). When the promoter region of the *S. coprophila* II/9-1 gene is transgenically introduced into *D. melanogaster*, it is transcriptionally responsive to ecdysteroids in the salivary gland, indicating that the ecdysteroid-inducible transcriptional machinery is conserved evolutionarily between the two species (Bienz-Tadmor *et al.*, 1991). However, there is no evidence that the DNA amplification is induced by 20E in flies or mediated by the ecdysteroid receptor.

In *Trichosia pubescens*, Amabis and Amabis (1984) found that ecdysteroid treatment of salivary glands generates both DNA and RNA "early" puffs, whose subsequent regression is accompanied by the appearance of other "late" DNA amplification and RNA puffs. Cycloheximide treatments after early puff appearance block late puff expansion. In this species, large puffs appear after considerable delay, and the appearance of early puffs is not obvious, suggestive of a single broad ecdysteroid peak, rather

than the two peaks that occur in *D. melanogaster* over the same developmental timespan. In this respect, the response pattern is comparable to *C. tentans*, which in turn relies upon an interplay of ecdysone and 20E to achieve ecdysteroid-induced regulation (Stocker and Pavan, 1977).

In yet another sciarid fly, *Bradysia hygida*, 20E induces DNA amplification and transcription of a temporally "late" puff gene (BhC4-1). When this gene is transgenically introduced into *D. melanogaster*, it retains its "late" puff characteristics in terms of salivary gland timing, but transcription of the gene is not blocked by repression of protein translation with cycloheximide, suggesting that the late induction is actually a form of derepression in the *D. melanogaster* salivary gland (Basso *et al*., 2002). This interpretation is also based on the observation that 20E exerts both repressive and inductive effects upon the protein composition of the *B. hygida* salivary gland during the fourth and final larval stage (de Carvalho *et al*., 2000).

As evidenced by the cases presented here, beyond the superficial similarity, there are numerous unsolved mysteries about the integration of ecdysteroid response into biological processes, especially when one considers that the most complete hierarchical comparisons so far involve only lepidopteran and dipteran species. Several ecdysteroid-inducible genes have been identified for the coleopteran, *T. molitor* (Mouillet *et al*., 1999), at least indicating that several of the orphan receptors involved in mediating ecdysteroid responses exist in more primitive insects. Further, the existence of an E78 ortholog in the filarial parasite, *D. immitis*, implies that at least portions of the hierarchy are conserved in other invertebrates (Crossgrove *et al*., 2002).

3.5.4.5. *In Vivo* Molecular and Genetic Analysis of EcR and USP

The pattern of EcR gene transcription during premetamorphic development fluctuates dramatically, with high levels accompanying each of the embryonic and larval molts, followed by peaks of expression during the prepupal and pupal-adult stages of metamorphosis (Koelle *et al*., 1991). Moreover, the EcR gene encodes three different isoforms with the A isoform's transcription governed by a promoter and two other isoforms (B1 and B2) generated by alternative splicing via a second promoter (Talbot *et al*., 1993). All three isoforms share a common sequence that includes a small portion of the A/B domain and the other domains, but the amino-terminal side of the A/B region for each isoform is unique. The A isoform predominates in fly tissues which undergo morphogenetic changes during metamorphosis, including the imaginal discs, the ring gland, the imaginal rings of the foregut, hindgut, and salivary gland (Talbot *et al*., 1993), and in a heterogeneous subset of neurons that degenerate after adult emergence (Truman *et al*., 1994) (see **Chapter 2.4**), whereas the B1 isoform is found in larval tissues including the salivary gland, the fat body, larval muscle (Talbot *et al*., 1993), and proliferative neurons (Truman *et al*., 1994).

Functional studies of EcR based on the isolation of mutations within the *D. melanogaster* gene have led to further insights about EcR's developmental role, and essentially confirmed its ecdysteroid-mediating function. As might be expected, null mutations of a common region in EcR, and thereby disrupt all three isoforms and result in embryonic lethality, whereas mutations that retain a reduced ability to mediate ecdysteroid responses allow mutant survival through some or all of the larval stages. Some of these weaker mutations affect nonconserved residues, but at least one of these prepupal lethal mutations involves a highly conserved phenylalanine in the DBD; conversely, there are nonconserved residues that cause embryonic lethality when substituted. One of the lethal mutations (A483T) replaces the amino acid residue that interacts with the SMRTER corepressor and is a conditional third instar lethal mutation. Presumably, the lability of the mutant protein disrupts the normal interaction between EcR and SMRTER at higher temperatures (29 °C). The A483T mutation (along with other EcR mutations; **Table 2**) also disrupts adult female fecundity at its restrictive temperature, indicating that the corepressor interaction is essential for at least late larval development and oogenesis (Bender *et al*., 1997; Carney and Bender, 2000). B-specific mutations cause early larval lethality (Schubiger *et al*., 1998); an A-specific EcR mutation reduces but does not eliminate mutant survival to the adult stage and disrupts the normal expression of EcRB1 (D'Avino and Thummel, 2000; Schubiger *et al*., 2003) (see **Chapter 2.4**). Other A-specific mutations cause pupal lethality (Carney *et al*., 2004). A gain-of-function mutation of *Dm*EcR (K497A) that dimerizes in the absence of hormone, possibly because of disrupted corepressor binding, has also been identified in cell cultures, though its potential *in vivo* effect is unknown (Bergman *et al*., 2004).

Over developmental time, the B2 isoform, when expressed under the control of a heat shock promoter, rescues larval development in EcR-null mutants, though heat shocks are required in each instar to accomplish it. The A and B1 isoforms rescue development through the first instar, but fail thereafter, suggesting that a common function is required

Table 2 A selected list of EcR mutations and their functional consequences. Mutations correspond to shaded residues in **Figure 4**

Mutation	*Species*	*Effect*
A393P	*C. fumiferana*	Destroys 20E response, but not nonsteroidal agonist response (Kumar *et al.*, 2002; Billas *et al.*, 2003). Impaired coactivator (GRIP1) interaction (*Cf*EcR only; Kumar *et al.*, 2002)
A398P	*H. virescens*	
A522P	*D. melanogaster*	
A534P	*A. aegypti*	
A559P	*B. mori*	
Y403A	*H. virescens*	Reduces nonsteroidal agonist response, but not 20E response (Billas *et al.*, 2003)
A483T	*D. melanogaster*	Conditional late larval lethal mutation; disrupts oogenesis (Li and Bender, 2000); binding site for SMRTER corepressor (Tsai *et al.*, 1999)
K497A, E	*D. melanogaster*	Constitutive transcriptional activity in cell culture (Bergman *et al.*, 2004)
Y611F	*D. melanogaster*	Elevated binding to *hsp27* EcRE in presence of ecdysone (Wang *et al.*, 2000)
F645A	*D. melanogaster*	Dimerizes normally but is not 20E inducible; dominant negative lethal mutation *in vivo* (Cherbas *et al.*, 2003)
W650A	*D. melanogaster*	No dimerization (Cherbas *et al.*, 2003)

during the first instar and more differentiated EcR functions are essential later. The rescued B2 transformants become sluggish during the wandering stage of the late third instar, then immobile, and eventually die (Li and Bender, 2000).

Isoform-specific mutations in conjunction with transformation rescue have further delineated EcR-based functions in fly development. As expected, an EcRB1-specific mutation disrupts developmental activities in those cells where it is expressed. For instance, the salivary gland's ecdysteroid-induced puffing is disrupted in B1 mutants (but not eliminated), and only transformation with EcRB1 restores normal puffing of various early and early-late genes, though B2 exerts a partial rescue. Similarly, B1-expressing abdominal histoblasts and midgut cells develop abnormally (Bender *et al.*, 1997). Neuronal remodeling during metamorphosis is disrupted in genetic mosaics that do not express either of the two B isoforms in proliferating neurons (Schubiger *et al.*, 1998) (see **Chapter 2.4**), but remodeling is rescued by the expression of either B isoform within these cells (Schubiger *et al.*, 2003). Remodeling is not disrupted in mutations of the early puff genes, indicating that this aspect of the cascade is not specifically tied to the failure of B isoform mutant effects (Lee *et al.*, 2000).

A related strategy for discriminating EcR functions involves introducing an isoform or fusion protein transgenically into flies, expressing the transgene ectopically, and then observing the dominant negative phenotypic consequences of such expression. At least three variations have been reported: (1) expression of a wild-type isoform ectopically under the control of an UAS promoter regulated by the yeast GAL4 transcription factor (Schubiger *et al.*, 2003), (2) the expression of a GAL4-EcR LBD fusion protein that forms an inactive dimer with cellular USP in a nonisoform specific manner (Kozlova and Thummel, 2002, 2003a), and (3) UAS-controlled expression of a dominant negative EcRB1 isoform (F645A in *D. melanogaster*) that forms an inactive dimer with intracellular USP, and is then tested for rescuability by the concomitant expression of a specific isoform (Cherbas *et al.*, 2003). In the case of wild-type overexpression, each isoform generates a unique pattern of phenotypes. Overexpression of EcRA suppresses posterior puparial tanning, and affects ecdysteroid-inducible gene expression in posterior compartments of the wing disc but does not affect viability. By contrast, overexpression of EcRB1 and B2 during puparial formation greatly reduces viability (Schubiger *et al.*, 2003) (see **Chapter 2.4**). Ectopic expression of a GAL4-EcR during the late third instar causes a failure of puparial contraction and cuticular tanning that resembles the traits displayed by mutant EcR larvae (Kozlova and Thummel, 2002). The isoform-specific rescue of the EcR^{F645A} mutants, however, reveals a poor correlation between tissue-specific effects and intracellular titers of each isoform, though the accumulation of disrupted responses in several individual tissues leads to a stage-specific developmental arrest in the third instar (Cherbas *et al.*, 2003).

Further insights about the functional differences associated with the *D. melanogaster* EcR isoforms will likely emerge by understanding the basis for isoform-specific mRNA transcription. Two promoters, one associated with the A isoform, and the other associated with the two B isoforms, regulate the appearance of these transcripts. Promoter segments responsible for high levels of EcRA expression during metamorphosis have been identified (Sung and Robinow, 2000). While the level of EcRA detected is homogeneous among those neurons which express

EcRA during metamorphosis, the underlying promoter regulation is surprisingly heterogeneous among them, indicating that the observed pattern of expression obscures an underlying regulatory complexity. A TGF-β/activin signaling pathway has been implicated in the regulation of EcRB1 transcription. In activin mutants, EcRB1 transcription is reduced and neurons in the mushroom bodies of the brain fail to undergo remodeling during metamorphosis. The expression of EcRB1 rescues the remodeling defects, indicating that EcRB1 levels are regulated through the activin signaling pathway (Zheng *et al*., 2003).

By comparison with EcR's complexity, the regulation of the *usp* gene in *D. melanogaster* is relatively simple, with no introns and no alternative splicing forms, though the profile is more complex in species with multiple USP isoforms (Jindra *et al*., 1997; Vogtli *et al*., 1999). In flies, the expression of USP through development is relatively stable, though it is unclear whether EcR or USP is the rate-limiting partner in developing tissues (Henrich *et al*., 1994). The *usp* gene is defined by several recessive early larval lethal mutations: three missense substitutions (usp^3, usp^4, and usp^5) that mutate amino acid residues in the USP DBD and directly contact phosphate residues in the DNA backbone, along with a nonsense mutation, usp^2, that truncates the DBD (Oro *et al*., 1990; Henrich *et al*., 1994; Lee *et al*., 2000). The null-usp^2 allele evokes a different effect on gene expression than the other *usp* alleles. Whereas all the mutations disrupt the normal repression of the BrC-Z1 isoform, only USP2 is incapable of activating BrC-Z1 transcription. USP3 and USP4 are also able to mediate ecdysteroid-induced gene transcription through an *hsp27* EcRE-regulated promoter (Ghbeish *et al*., 2001).

This dual capability has been analyzed *in vivo* during ommatidial assembly and differentiation in the eye disc. Briefly, the differentiation of the eight retinula cells in each of the 700 or so ommatidia that become the compound eye occurs through the recruitment of undifferentiated cells as a wave moves from the posterior to anterior end of the eye disc. Cells along this progressing wave, the morphogenetic furrow, undergo a host of transcriptional changes and some aspects of the process are ecdysteroid-dependent *in vitro*. Furrow advancement accelerates in mutant *usp* patches on the eye disc (Zelhof *et al*., 1997), whereas an ecdysteroid deficit retards its advancement (Brennan *et al*., 1998). The apparently paradoxical action results from the failure of a repressive *usp* function as evidenced by the abnormal appearance of Br-C Z1 expression in mutant patches lying along the front of the moving furrow. The usp^2 allele causes an absence of Z1 behind the furrow, where it is normally present, further demonstrating the dual roles. USP has been similarly implicated in both wing margin bristle differentation (Ghbeish and McKeown, 2002), and the repression of premature neuronal differentiation in the wing imaginal discs (Schubiger and Truman, 2000) (see **Chapter 2.4**). The maintenance of USP3 and USP4 activation functions likely explains the normal appearance of mutant *usp* imaginal clones (Oro *et al*., 1992).

Maternal contribution of normal *usp* transcript is essential for the completion of embryogenesis (Oro *et al*., 1992). Mutant *usp* larvae are rescued through the third instar with a USP connected to a heat shock promoter. The lethal phenotype of these partially rescued larvae is reminiscent of the effects seen with larval EcR mutations and internal morphology is similar at the time of larval arrest. Only the *usp* mutants, however, develop a supernumerary larval cuticle and fail to wander off the food (Hall and Thummel, 1998; Li and Bender, 2000). DHR38 mutants also undergo abnormal cuticle apolysis (Kozlova *et al*., 1998), suggesting that the DHR38/USP dimer may be essential for this aspect of premetamorphic development, rather than the EcR/USP dimer.

It is beyond the realm of this chapter to explore the effects of ecdysteroid-inducible genes in depth and the reader is directed to other reviews (Henrich *et al*., 1999; Riddiford *et al*., 2000; Thummel, 2002). Isoform-specific mutational analysis of ecdysteroid-responsive genes has generally confirmed essential roles at metamorphosis with the two isoforms of E74 (Fletcher *et al*., 1995), two of the E75 isoforms (Bialecki *et al*., 2002), DHR3 (Lam *et al*., 1999), and the *β*FTZF1 isoform (Broadus *et al*., 1999). The complex genetic complementation of several Br-C mutations (Kiss *et al*., 1988) has been associated with each of four isoforms (Z1–Z4; Bayer *et al*., 1997). The *npr1* (nonpupariation) third instar lethal mutations of Br-C fail to complement all other alleles by impairing a common and essential premetamorphic function. Some Br-C mutations affect the gene's own expression (Gonzy *et al*., 2002), consistent with predictions of the Ashburner model. As noted elsewhere, Br-C isoforms play a variety of inductive and repressive roles, often through switchover of isoform expression, in a large spectrum of premetamorphic processes.

3.5.4.6. Ecdysteroid Receptor Cofactors

As noted earlier, the ecdysteroid receptor is part of a complex of proteins which affect both its inductive

and repressive transcriptional functions. In the case of Hsc70, a chaperone that physically interacts with *Dm*EcR, this functional importance is demonstrated by the genetic interaction between EcR and Hsc70 mutations (*hsc4* gene) in *D. melanogaster*. Trans-heterozygotes for these two mutations develop severely blistered wings and bent legs typically associated with the mutational impairment of EcR function (Bender *et al*., 1997; Arbeitman and Hogness, 2000).

Based on findings from experiments with vertebrate nuclear receptors (see **Chapter 3.6**), transcriptional cofactors and their roles have begun to be recognized and explored; the process of eye ommatidial differentiation during the third instar of *D. melanogaster* that was described earlier has become the focus of efforts to understand the role of cofactors in development. The dominant negative EcR^{F645A} mutation severely disrupts eye development (Cherbas *et al*., 2003; Sedkov *et al*., 2003), and USP function is also required for normal furrow progression (Zelhof *et al*., 1997).

One cofactor implicated in the process is the product of the trithorax-related (*trr*) gene, a histone methyltransferase that conceivably plays a role in remodeling the chromatin in promoter regions, just as vertebrate factors do to facilitate receptor-mediated transcription (Stallcup, 2001). The role of TRR as an ecdysone-dependent coactivator is evidenced by the fact that it is recovered as part of a complex that includes EcR and a trimethylated form of the histone-3 protein (presumably modified by TRR) from the ecdysteroid inducible promoter of the *Drosophila hedgehog (hh)* gene in extracts derived from 20E challenged S2 cells. The methylation is reduced in complexes taken from *trr* mutant embryos. Further, the trans-heterozygotic combination of a *trr* mutation and the EcR^{F645A} mutation causes almost complete lethality, revealing an essential *in vivo* interaction. The aforementioned Hedgehog (Hh) protein regulates the progression of eye cell differentiation, and *trr*-mutant somatic cell clones express Hh at reduced levels. It follows that TRR is normally a coactivator associated with elevated ecdysteroid-inducible activity leading to higher Hh levels.

EcR retains its repressive capabilities in the absence of its inducible activity, and another cofactor, the corepressor SMRTER, has also been implicated in the regulation of Hh expression and eye differentiation. The lethal and mutant phenotypic effects of the dominant negative EcR^{F645A} mutation are reversed by a hypomorphic mutation of the *Smr* corepressor (i.e., a partial loss of repression), just as EcR mutant effects are overcome by increasing TRR coactivator activity (Sedkov *et al*., 2003).

Both TRR and SMRTER carry the LXXLL amino acid motifs (L refers to leucine and X refers to any amino acid) associated with nuclear receptor interactions, and physical interaction sites with EcR have been mapped in both cases (Tsai *et al*., 1999; Sedkov *et al*., 2003). Moreover, the SMRTER interactive site in *Dm*EcR has been mapped to an amino acid residue in helix 5 that when mutated (A483T) results in conditional larval lethality (Bender *et al*., 1997; Tsai *et al*., 1999). Another *Drosophila* coactivator, Taiman (TAI), was first identified in a screen for mutations that disrupt oogenesis. TAI resembles a human ortholog (AIB1) belonging to the p160 steroid receptor coactivator family (SRC), whose members are typified by a basic helix-loop-helix (bHLH) domain, a PAS domain of unknown function, several LXXLL motifs associated with nuclear receptor interaction, and several glutamine-rich stretches. These proteins form a bridge between hormone receptors, chromatin modifying enzymes such as the histone acetyl transferases, and the transcriptional machinery. TAI expression colocalizes with EcR and USP in the border cells of the ovary and colocalizes with USP on the polytene chromosomes of *Drosophila* larval salivary glands. TAI also elevates ecdysteroid-inducible transcription in a cell culture and coprecipitates with EcR, but not USP (Bai *et al*., 2000). Its role in premetamorphic processes has not yet been elucidated.

Still another EcR-interacting protein containing the LXXLL motif, *rigor mortis* (*rig*), is required for ecdysteroid signaling during larval development. Mutant *rig* larvae fail to survive beyond the advent of metamorphosis, while displaying phenotypes resembling other mutations defective in ecdysteroid synthesis or response. Rig is required as a coactivator for induction of the E74A isoform which normally appears as ecdysteroid titers increase, but is not required for E75A, EcR, or USP transcription; the effect on transcription is likely to be indirect since Rig contains no DNA-binding motifs. The protein interacts physically with EcR and USP, and also with the orphan receptors DHR3, βFTZ-F1, and SVP. Even when helix 12 is deleted from βFTZ-F1, its interaction with Rig is detectable, suggesting that the relationship between Rig and nuclear receptors is ligand-independent (Gates *et al*., 2004). A *D. melanogaster* corepressor, Alien, that is highly conserved phylogenetically, also interacts with several receptors, including EcR, SVP, and βFTZ-F1 (but not DHR3, DHR38, DHR78, or DHR96; Dressel *et al*., 1999). No mutations of Alien have been reported so far.

The pattern of receptor interactions seen with TAI, Rig, and Alien suggests that a level of regulation

remains to be elucidated in connection with the ecdysteroid hierarchy. This is further highlighted by the effects of another cofactor, Bonus (Bon), which belongs to a class of proteins (TIF1) that do not bind to DNA directly, but which repress transcriptional activity. Homozygous *bon* mutants display many of the defective *β*FTZ-F1 phenotypes noted earlier (Broadus *et al.*, 1999), and Bon physically interacts with helix 12 of *β*FTZ-F1 via an LXXLL motif. In some *bon* mutants, transcript levels of EcR B1, E74A and B, and BR-C are reduced, but DHR3 transcript levels are elevated (Beckstead *et al.*, 2001). Non-DNA binding cofactors, MBF1 and MBF2, associated with *Bombyx* *β*FTZ-F1 activity have also been identified which interact with the TATA binding protein to induce transcription (Li *et al.*, 1994).

Finally, it is notable that the methoprene-resistant (Met) mutation in *D. melanogaster* defines a gene which specifies another bHLH-PAS transcription factor (Ashok *et al.*, 1998) (see **Chapters 3.7** and **3.9**). Cellular extracts from flies homozygous for Met mutations show little binding to the juvenile hormone analog methoprene (Shemshidini and Wilson, 1990). The implications of this identity and its significance for explaining the modulatory effects of JH on ecdysteroid-inducible transcriptional activity will be addressed later.

3.5.4.7. Orphan Receptor Interactions with EcR and USP

In addition to those players which have been tied directly to the transcriptional response elicited by the EcR/USP heterodimer (DHR3, E75, E78, *β*FTZF1), several other nuclear receptors also modulate receptor activity by either dimerizing directly with USP, or by competing for EcR/USP promoter sites.

The DHR38/USP interaction is particularly interesting because *in vitro* results suggest that it is this "receptor" complex that responds to a broad spectrum of ecdysteroids, including many known to exist in *D. melanogaster* larvae. Further, DHR38 mutations disrupt cuticle formation, as do *usp* mutations, but EcR mutations do not impair this aspect of development, leaving open the possibility that this aspect of ecdysteroid regulation does not involve EcR at all (Hall and Thummel, 1998; Kozlova *et al.*, 1998). DHR38 is broadly expressed but transcript levels appear to be in low abundance (Sullivan and Thummel, 2003), though the DHR38/USP heterodimer is more responsive to 20E than EcR/USP (Baker *et al.*, 2003). In any case, the mechanism of action is novel, since the transcriptional activation via DHR38/USP is not associated with a physical ligand interaction.

A similar dimer between AHR38 and *Aa*USP has been noted prior to vitellogenesis in *A. aegypti*. The nonresponsive heterodimer is displaced by the EcR/USP heterodimer in response to a 20E titer peak following a bloodmeal (Zhu *et al.*, 2000) (see **Chapter 3.9**). As noted earlier, USP also dimerizes with SevenUp (SVP), the aforementioned ortholog of COUP-TF. As the 20E peak that stimulates *A. aegypti* vitellogenin expression ensues, a similar competition between EcR and SVP for USP as a heterodimeric partner leads to a downregulation of *A. aegypti* vitellogenin gene transcription after egg-laying (Zhu *et al.*, 2003a), illustrating a mechanism by which an ecdysteroid response can be terminated.

Ectopic expression of the svp^+ gene in flies causes lethality, but this effect can be rescued by simultaneous ectopic expression of usp^+ (Zelhof *et al.*, 1995a). This interaction apparently is a relevant aspect of photoreceptor differentiation, since both SVP and USP function are essential for this process to occur normally (Mlodzik *et al.*, 1990; Zelhof *et al.*, 1997). The potential relevance of the SVP/USP interaction has also been established by demonstrating that SVP competes with EcR for USP's partnership, and thereby reduces ecdysteroid-induced transcription in cell cultures. Further, the functional SVP/USP dimer preferentially interacts with DR1 DNA elements, whereas the EcR/USP dimer interacts with the Eip28/29 element.

Still another orphan receptor that is essential for normal metamorphosis in flies is DHR78. Mutations of this receptor cause late larval lethality, disruptions of the tracheal system, and the impairment of EcR, E74B, and BR-C transcription. DHR78 binds to numerous ecdysteroid inducible sites in salivary glands (Fisk and Thummel, 1998; Astle *et al.*, 2003). DHR78 inhibits 20E-dependent induction of transcription in cell culture assays (Zelhof *et al.*, 1995b) and it has been proposed that DHR78 activity may interact with an "upstream" ligand in the period that precedes the late third instar ecdysteroid peak to prime a later ecdysteroid response (Fisk and Thummel, 1998). A *Bombyx* ortholog, BHR78, has been shown to dimerize directly with BmUSP (Hirai *et al.*, 2002) suggesting that DHR78 may block 20E-dependent transcription by competing for USP with EcR.

3.5.4.8. Ecdysteroid Action and Other Developmental Processes

The ecdysteroid response is highly heterogeneous among cell types, owing to differences in the

quantitative levels of EcR and USP isoforms, rates of 20E conversion from ecdysone, 20E metabolism and cellular exclusion, and yet it is evident that the circulation of ecdysteroids in the insect hemolymph provides the organism with a means to coordinate its individual developmental programs. Therefore, it is expected that ecdysteroids set off general responses and also specific responses that involve either EcR and USP or targets that are regulated by them.

For organismal investigations, the dramatic changes associated with the late larval ecdysteroid peak in *D. melanogaster* evoke substantial changes in transcript levels which can be detected using genomic approaches. As already noted, a combination of standard technology and a genomic outlook has motivated the assembly of a detailed profile of orphan receptor transcript levels through preadult development (Sullivan and Thummel, 2003). A limitation of the whole body approach is evident in the case of DHR38, which is widely expressed but at such low levels that the transcript is barely evident on Northern blots. An earlier study using subtractive hybridization led to the characterization of several ecdysteroid-inducible genes, most of which were unknown and not associated with ecdysteroid-inducible events directly (Hurban and Thummel, 1993). Screens of hematopoietic Kc cells (Savakis *et al.*, 1980) and imaginal discs (Apple and Fristrom, 1991) have yielded several ecdysteroid-dependent genes which do not overlap with those recovered from other screens, and these transcripts are largely associated with tissue-specific responses. However, while the timing of early ecdysteroid gene expression is delayed in the discs (Huet *et al.*, 1993), at least one ecdysteroid-responsive pupal cuticle gene, EDG84A, is regulated by FTZ-F1, which as noted, also regulates metamorphic processes in the salivary gland (Murata *et al.*, 1996).

Microarray analysis has been used more recently to investigate the changes in transcription on a genome-wide basis, using the onset of the white prepupal (puparial) stage as a reference point. The early puff genes change in a predictable, ecdysteroid-regulated manner, and genes involved in processes such as myogenesis, apoptosis, and imaginal disc differentiation are upregulated at appropriate times during the period. As ecdysteroid levels peak, transcription of most genes encoding glycolytic enzymes are substantially reduced, as are genes whose enzymatic products regulate the citric acid and fatty acid cycles, oxidative phosphorylation, and amino acid metabolism (White *et al.*, 1999). Adult flies heterozygous for a lethal EcR mutation survive longer than wild-type flies and show greater resistance to oxidative stress, heat, and dry conditions, though activity levels are normal and a possible connection to metabolic function has not been made (Simon *et al.*, 2003).

Important mechanistic activities at the cellular level, however, will continue to require careful functional analysis. In the case of eye differentiation in flies, morphogenetic furrow movement during the late third instar is dependent on 20E, but not on normal EcR gene activity (Brennan *et al.*, 2001). The repressive action of USP described earlier for this process (Ghbeish and McKeown, 2002) is offset by the positive regulation of Hedgehog (Hh) transcription that involves EcR (Sedkov *et al.*, 2003). Hh, in turn, facilitates a switchover from the Z2 to the Z1 isoform at the ecdysteroid-responsive BR-C gene locus. The temporal coordination of hormonal signaling with the regulatory activities along the furrow, therefore, provide a balance of signals that both stimulates morphogenetic furrow movement (in the form of EcR-mediated Hh expression) and regulates its rate of progression (in the form of a repressive USP function). The mechanism of furrow movement is not fully elucidated, and it is conceivable that a second hormonal signaling pathway is involved in the process.

The interaction between JH and ecdysteroid action remains elusive, despite the clear recognition that there must be cross-talk between these pathways. The JH analog methoprene induces several disruptions of the central nervous system that resemble those caused by mutations of the BR-C gene. These defects are not seen in flies homozygous for the methoprene-resistant (MET) mutation (Restifo and Wilson, 1998).

3.5.4.9. Juvenile Hormone Effects upon Ecdysteroid Action

A central tenet of insect biology is that ecdysteroids mediate larval-larval molts in the presence of the sesquiterpenoid, JH (see **Chapter 3.7**). In the absence of JH, by contrast, ecdysteroid induces a larval-pupal transition. Implicit in this view is the recognition that JH via its receptor competes with the EcR/USP dimer at an EcRE (Berger *et al.*, 1992) or modifies components of the ecdysteroid receptor itself (Jones *et al.*, 2001; Henrich *et al.*, 2003). Nevertheless, no uniform explanation for the action of JH, alone or in conjunction with ecdysteroids, has been forthcoming.

The structural similarity of 9-*cis* retinoic acid, the cognate ligand of vertebrate RXR, with JH inspired experiments to test the possibility that the insect RXR ortholog, USP, is the JH receptor, and like RXR, switches between a homodimeric and heterodimeric state to process incoming hormonal

signals. This enticing possibility is further bolstered by the observation that RXR is inducible by binding to the acid metabolite of the JH analog, methoprene (Harmon *et al*., 1995). Jones and Sharp (1997) reported that a *Drosophila* USP fusion protein binds to JH forms found in flies, as measured by the dose-dependent suppression by JH3 and JH3-bis epoxide on the fluorescence of tryptophan residues in the ligand binding domain of USP. Later studies have demonstrated that purified USP fusion proteins exist in homodimeric and homotetrameric forms which show a saturable ability to bind to JH3, with about 50% binding at 4 μM, while the closely related farnesol exerts no effect. Using nuclear extracts from the lepidopteran Sf9 cell line, it was further shown that USP binds specifically as a homodimer to a direct repeat response element separated by 12 nucleotides (DR12). Further, JH3 strongly induces a reporter gene in which the DR12 element is attached to the core promoter of the gene encoding the *Trichoplisia ni* JH esterase (Jones *et al*., 2001). A DR4 element in the *C. fumiferana* JH esterase gene promoter is induced by JH1 and suppressed by 20E, suggesting that an interaction between these hormones occurs at the DNA level (Kethidi *et al*., 2004). The biochemical examination of these promoters, along with those of JH-inducible genes found recently in cell cultures through microarray analysis, will hopefully bring a convergence of views on JH action (Dubrovsky *et al*., 2000).

Along a different line of reasoning, experiments have been undertaken based on the sequence similarity between the EcR LBD and the vertebrate FXR LBD, which surprisingly, is responsive to JH3 in the 10–50 μM range with an RXR dimer partner in mammalian cell cultures (Forman *et al*., 1995). When tested in this regime, JH3 potentiates the ability of the EcR/USP complex to induce a weak transcriptional induction via an *hsp27* EcRE in the presence of submaximal muristerone A levels. The potentiation apparently requires prior binding of EcR to ecdysteroids and there is no evidence yet that JH3 is binding with USP in this assay, and no response is noted with EcR/USP to bile acid, the most potent FXR activator. When tested with 20E, only EcRB2 among the three *Drosophila* isoforms is additionally potentiated with JH3 (Henrich *et al*., 2003), and, as noted, the B2 isoform is the only one capable of rescuing larval development in EcR mutants (Li and Bender, 2000). The potentiation is not analogous to the responsiveness of an EcR/RXR heterodimer described earlier (Saez *et al*., 2000), and the low ecdysteroid levels which accompany JH titers during larval development suggests its possible biological relevance. In both *Drosophila* and *Manduca*, one of the isoforms of Broad (Z1) is ectopically induced in cuticle by the application of JH analogs, further supporting the possibility that JH acts directly upon the ecdysteroid receptor's transcriptional capability (Zhou and Riddiford, 2002), since the BR-C gene is a direct target of the receptor in both *Drosophila* and *Manduca*.

In reality, differences such as the promoter and receptor constructs among the experimental regimes leave open the possibility that USP acts by multiple mechanisms, particularly if one considers the possibility that posttranslational modifications such as phosphorylation also can modify receptor activity. Possibly distinct roles of USP during larval and metamorphic development are evidenced *in vivo* by the fact that a chimeric USP transgene (in which the *Drosophila* USP LBD is replaced by the equivalent domain from *C. tentans*) completely rescues larval development in *usp* mutants that otherwise die in the first instar. Such genetically rescued larvae, however, suddenly die as the onset of the prepupal stage approaches (Henrich *et al*., 2000). Another potentially important factor is the protein defined by the Methoprene-tolerant (Met) mutation that belongs to the bHLH-PAS family of transcription factors, and includes several cofactors known to interact with nuclear receptors (Ashok and Wilson, 1998). The effects of Met upon the ecdysteroid receptor await further experimentation in *Drosophila* and other insects.

JH3 plays an essential role for the translation of *β*FTZ-F1 from existing transcripts in the fat body of newly emerged *A. aegypti* females. In turn, FTZF1 activity is required for the subsequent transcription of the mosquito "early puff" genes regulating vitellogenesis (Zhu *et al*., 2003b) (see **Chapter 3.9**). While this may be seen as another mode of action, the effect on *β*FTZF1 translation may be indirect, that is, JH3 may regulate the transcription of genes whose products play a role in mRNA stability and/or protein translation.

In summary, the diverse functional effects of JH upon ecdysteroid-inducible gene expression have elicited several possible mechanisms from investigators over the years. As it becomes increasingly apparent that EcR and USP are the two most recognizable components of a protein complex of diverse functional capability, it seems highly plausible that there is not a single JH receptor, but rather, a JH receptive protein complex (or complexes).

3.5.5. Prognosis

An explosion of information about the ecdysteroid receptor has occurred recently which will

undoubtedly influence the field far into the future. There are three levels of progress that will be central to the development of the field: (1) continued progress on understanding the biological action of ecdysteroids using functional genomics and genetics in *D.melanogaster*, (2) the adaptation of transgenic and genomic methods into receptor studies of other insects, and (3) continued modeling of insect receptor complexes along with tests of these models through both *in vitro* and *in vivo* experimentation.

The emergence of clever new methodologies, notably the *in vivo* lacZ reporter system reported by Kozlova and Thummel (2003b), provides *in vivo* tools that overcome the limitations of biochemical isolation and testing from flies. Microarray analysis has already been employed to investigate changes in gene transcription at the onset of metamorphosis (White *et al*., 1999) and to compare expression in Kc167 and SL2 cell lines (Neal *et al*., 2003). Microarray analysis has also been employed in *D. melanogaster* to follow expression events throughout larval and metamorphic development. The results suggest that while the larval stage is relatively quiescent, there are unique patterns of expression associated with this early developmental time which in some cases, may prove to be repressive functions (Arbeitman *et al*., 2002). In this respect, microarrays also may prove important for gaining a better grasp of JH's mode of action (Dubrovsky *et al*., 2000) during larval stages. Inevitably, the genomic approach will unravel entire gene networks that interact with and operate within the ecdysteroid-regulated hierarchy (Arbeitman *et al*., 2002; Stathopoulos and Levine, 2002). In any event, investigating the entire genome is important for identifying temporal connections at a gene expression level which potentially coincide with important functional relationships, as the connection between the glycolytic pathway and the onset of metamorphosis has already exemplified (White *et al*., 1999). Sooner rather than later, it is likely that genome-wide approaches will be applied to identify EcR and/or USP binding sites (Ren *et al*., 2000).

Another feature of ecdysteroid action which has received virtually no attention is the role that nutritional and cellular states play in determining and modifying ecdysteroid action (Zinke *et al*., 2002). As the case with glycolysis shows, it seems inevitable that a relationship exists here, given that the most important problem for premetamorphic insects stems from their need to process nutrients as they grow and undergo molting. The role of orphan receptors and their ligands seems an obvious place to explore this possibility, since most of the identified orphans among vertebrates have proven to be responsive to a variety of dietary compounds and intracellular metabolites, including EcR's vertebrate relatives, FXR and LXR.

The regulation of EcR and USP expression has begun to be undertaken and should also lead to important insights about endocrine regulation generally, and the interaction of ecdysteroid regulation with other biological processes (Sung and Robinow, 2000; Zheng *et al*., 2003). EcR undergoes fairly dramatic fluctuations in transcription, though little is known about the relative titers of EcR and USP intracellularly (Koelle *et al*., 1991). In other words, it is not clear which one of the two is rate-limiting in any given cell type, and thus, a quantitative question remains to be fully considered. In fact, there has been a tendency to ascribe regulation to the roles of individual players, without regard to the fact that cellular protein titers, ligand titers, rate of metabolism, and the relative affinity of promoter elements all play a role in determining the level of transcriptional response at any given gene at any given time. When ecdysteroid action is viewed as a challenge of cellular equilibrium, it is seen as a continuous and interactive process rather than a directed and responsive one. Interestingly, there are still unanswered questions about ecdysteroid regulation within the *Drosophila* salivary gland hierarchy which will be particularly useful for examining ecdysteroid response and processing, particularly with the judicious use of transgenic constructs.

A second important cornerstone for future progress will depend upon a more complete depiction of ecdysteroid receptor function among the insect orders. A survey of known EcR and USP sequences shows that only Diptera and Lepidoptera are extensively represented at this time. Based upon the variations in agonist responsiveness already discovered among the insect receptors in these two orders alone, the need for obtaining and testing other insect receptors is plainly obvious.

The ability to assess the effects of EcR, USP, and genes targeted by the ecdysteroid receptor in other insects will be greatly enhanced by continued development of transformation procedures. The ability to produce "null" mutations via RNA interference with transgenic constructs will be particularly important for assessing functional processes in other insects. Uhlirova *et al*. (2003) illustrated this possibility by showing that Sindbis virus-induced transformation with an RNAi eliminates Br-C expression in *Bombyx mori*. The interference exacerbates the same developmental defects in *Bombyx* as previously noted for the effects of Br-C null mutations in flies.

Related to the discovery and characterization of ecdysteroid responses in insect processes will be the

continued examination of the insect receptors themselves. The use of chimeras and mutational analysis, in conjunction with the predictive powers provided by improved modeling and crystal structures, will lead to further insights concerning the capabilities of receptor function and its response to ligands, which may include a broad spectrum based on the flexibility of its ligand-binding pocket (Billas *et al*., 2003). Many mutations affect receptor function nonspecifically (Bender *et al*., 1997; Bergman *et al*., 2004), and site-directed mutagenesis provides a particularly useful approach for finding mutations that specifically disrupt EcR and USP subfunctions essential for interpreting receptor function in cellular and *in vivo* systems.

In summary, the information reported here represents only a fraction of the progress on ecdysteroid receptor action that has taken place over the last 20 years. The convergence of research interests mentioned at the outset has created a synergy among approaches that will continue to yield important new insights about endocrine action and its effects on development, new possibilities for insecticidal discovery, and new applications for the use of ecdysteroid-regulated transcriptional cell systems.

Acknowledgments

The author wishes to thank Drs. Dino Moras, Markus Lezzi, and Fraydoon Rastinejad for contributing illustration figures for this chapter. The author also acknowledges Drs Margarithe Spindler-Barth, Klaus Spindler, Markus Lezzi and Jean-Antoine Lepesant for useful discussions related to the material presented in this manuscript, along with Dr. Larry Gilbert for his advice on the writing and his friendship. The author is responsible for any inaccuracies in the content and apologizes for the exclusion of many excellent contributions because of space constraints. 3.6 Evolution of Nuclear Hormone Receptors in Insects

V Laudet and F Bonneton, Ecole Normale Supérieure de Lyon, Lyon, France

3.6.1. Introduction

Nuclear receptors form a superfamily of ligand activated transcription factors, which regulate various physiological functions from development or reproduction to homeostasis and metabolism (Laudet and Gronemeyer, 2002). This superfamily is present in all metazoans, and only in metazoans – no nuclear receptors have been found in the complete genome sequences currently available for plants, fungi, or unicellular eukaryotes (Escriva *et al.*, in press). In insects, nuclear receptors are implicated in embryogenesis as well as in the control of the postembryonic development, namely molting and metamorphosis (Kozlova and Thummel, 2000) (see **Chapters 3.3** and **3.5**). One of the most important insect hormones, 20-hydroxyecdysone (20E) is a ligand for a nuclear receptor, the ecdysone receptor (EcR) (Koelle *et al.*, 1991) (see **Chapter 3.5**). Although EcR is commonly called the ecdysone receptor, it is really the receptor for the principal molting hormone of insects, 20E. Ecdysone is in most cases the precursor of 20E. Although it is strongly debated, it is interesting to note that several studies have suggested that juvenile hormone (JH), a hormone that counteracts the action of ecdysone, might also act through nuclear receptors (Jones and Sharp, 1997) (see **Chapter 3.7**). It is of note that the superfamily contains not only receptors for known ligands but also a large number of so-called orphan receptors for which ligands do not exist or have not been identified. It is not known whether all of these orphan receptors indeed have a ligand, if they activate transcription in a constitutive manner, or if they have alternative transcriptional regulation mechanisms (Giguere, 1999). In insects, many orphan receptors are direct target genes of the EcR and participate in the gene regulatory hierarchy that controls metamorphosis.

Nuclear receptors are modular proteins, with three major domains arranged linearly from the N-terminus to the C-terminus (**Figure 1**). At the N-terminus there is a transactivation domain, most often called AF-1, which is of variable length and sequence in the different family members and which is recognized by other proteins in the transcription complex. The DNA binding domain (DBD), the site for specific interaction with DNA, is in the mid region of the protein and harbors two zinc finger motifs common to all members of the family. This domain is absent in two divergent members of the superfamily DAX-1 and SHP that are found only in vertebrates (Laudet and Gronemeyer, 2002). The C-terminal contains the ligand binding domain (LBD), whose overall architecture is well conserved between the various family members but which is nonetheless different enough to permit the high degree of ligand specificity characteristic of each member of the family. This domain harbors a ligand dependent activation function, called AF-2, that is responsible for the recruitment of transcriptional coactivators. As with DBD, the LBD is absent in

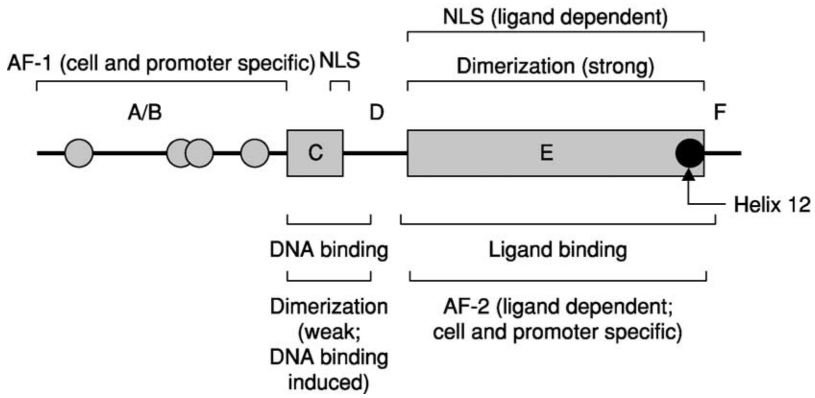

Figure 1 Schematic illustration of the structural and functional organization of nuclear receptors. The evolutionary conserved regions C and E are indicated as boxes and a black bar represents the divergent regions A/B, D, and F. Note that region F may be absent in some receptors. The functions of the domains are depicted below and above the scheme; most of these are derived from analyses of vertebrate receptors. Within the transcription activation functions, AF-1 and AF-2, autonomous transactivation domains have been defined in most receptors. These are depicted as circles in the A/B and E domain. The activation domain of the E region has been mapped within the C-terminal helix 12. Note that there are many receptor genes that encode different isoforms harboring different A/B regions, and thus different AF-1 and activation domains.

some divergent members of the superfamily such as the Knirps group in insects (Laudet and Gronemeyer, 2002).

The three-dimensional structure of the LBD has been determined for several nuclear receptors, including both unliganded (apo) or liganded (holo) forms, allowing increased understanding of the mechanisms involved in ligand binding and transactivation functions (**Figure 2**). Interestingly, the structure of the EcR-USP LBD heterodimer from the moth *Heliothis virescens* has recently been established (Billas *et al.*, 2003). These crystal structures show that the E domain undergoes a major conformational change upon ligand binding, allowing the interaction with coactivators and the transactivation of target genes. Many nuclear receptors are transcriptional silencers in the absence of ligand (apo-receptor) as a result of interaction with intermediary factors (i.e., corepressors). The determination of the crystal structure of nuclear receptors has shown that the LBD region is made up of a three-layered α-helical antiparallel sandwich of 11–12 helices forming a hydrophobic pocket (Wurtz *et al.*, 1996). Upon ligand binding (holo-receptor), the ligand makes different contacts with amino acid residues, promoting a conformational change that closes the “lid” (helix 12, H12) on the pocket and the corepressor complex dissociates. Thus, the activation domain within the H12 (AF2-AD) is able to interact with coactivators and promotes transcription of target genes. The conformational change of the LBD upon ligand binding is therefore necessary for the transactivation function of nuclear receptors (Steinmetz *et al.*, 2001; Laudet and Gronemeyer, 2002).

Nuclear receptors bind as homodimers or heterodimers to the regulatory regions of target genes (usually to the sequence PuGGTCA) called the hormone response element (HRE) (Laudet and Gronemeyer, 2002) (see **Chapter 3.5**). However, mutation, extension, and duplication, as well as distinct relative orientations of repeats of this motif, generate response elements that are selective for a given (class of) receptor(s). For example, steroid receptors bind as homodimers to HREs containing two core motifs separated by 1–3 nucleotides and organized as palindromes. Other receptors (e.g., RARs, TRs, HR38) heterodimerize with retinoid X receptors (RXRs, homologous to the insect *USP* gene) and bind to direct repeats (DRs) of the core motif. The spacing between the two halves of the DR dictates the type of heterodimer that will bind (e.g., a DR separated by five nucleotides (DRs) will be recognized by RXR:RAR and a DR4 by RXR:TR). Some receptors, such as the FTZ-F1, HR3, or E75 orphan receptors, can bind to DNA as monomers through a single core sequence. In this case, an A/T-rich region 5′ to the core element governs the binding specificity (Laudet and Adelmant, 1995).

The development of nuclear receptor research has largely been driven using data from mouse and *Drosophila* and it is interesting to note that the knowledge from these two organisms are largely complementary. In the mouse, many *in vitro* functional data are available and much effort has been deployed to analyze the mode of action of nuclear

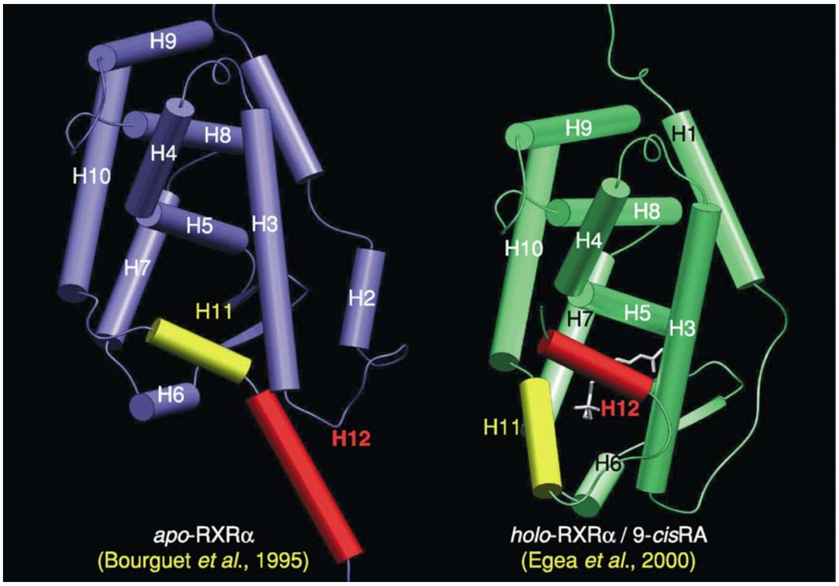

Figure 2 Three-dimensional structure of RXR in the apo or holo form. There are 11 helices that form a compact structure with a ligand binding pocket, the size of which varies between the various family members. The entrance to the pocket is guarded by a twelfth helix (H12), which forms a movable lid over the pocket and contains residues critically required for the function of AF2. The orientation of H12 is determined by the size and shape of the ligand occupying the pocket. In most cases, without ligand the LBD interacts with corepressors through a region called the CoRNR box in the region of helices H3 and H4. The ligand promotes a complex conformational change inducing the repositioning of H12, modifying the CoRNR box and thus leading to corepressor complex dissociation. This repositioning of H12 also allows the recruitment of coactivators involving the interaction with short LxxLL-like motifs called ''NR boxes'' present in most coactivators. The LxxLL motif recognizes a hydrophobic cleft formed by H3, H4, and H12 that has an important role in stabilizing this LxxLL-LBD interaction. The conformational change of the LBD upon ligand binding is therefore necessary for the transactivation function of NRs. (Data from Bourguet, W., Ruff, M., Chambon, P., Gronemeyer, H., Moras, D., **1995**. Crystal structure of the ligand-binding domain of the human nuclear receptor RXR-alpha. *Nature 375*, 377–382; and Egea, P.F., Mitschler, A., Rochel, N., Ruff, M., Chambon, P., *et al.*, **2000**. Crystal structure of the human RXRα ligand-binding domain bound to its natural ligand: 9-cis retinoic acid. *EMBO J. 19*, 2592–2601.)

receptors. Indeed, much of our knowledge on how nuclear receptors modulate transcription comes from studies on mammalian cell systems. In contrast, *Drosophila* work has provided essentially an *in vivo* oriented picture of the developmental role of nuclear receptors. Nevertheless, two important perspectives are missing from the field. First, very few structure/function analyses are available for insect (including *Drosophila*) nuclear receptors, most often what we know of their mode of action being derived from data obtained on mammals. This obviously hampers our global understanding of insect nuclear receptor action *in vivo*. Second, most of the data concerning nuclear receptors in insects arise from very few model systems, mainly *Drosophila* and other Diptera or lepidopterans such as *Bombyx mori* and *Manduca sexta*.

Taking these limitations into account, this chapter aims to put our current knowledge of insect nuclear receptors in a broader evolutionary perspective. This will be done first by discussing insect nuclear receptors in the context of metazoan phylogeny and evolution of the whole nuclear receptor superfamily. In the second part, we focus on the evolution of nuclear receptors in arthropods, providing specific data on liganded and orphan receptors in this phylum. Nevertheless, we must emphasize that an enormous amount of functional, genetic, and structural data is available on nuclear receptors and it is unrealistic to attempt to present a complete view of this exponentially expanding field. The interested reader can find several excellent reviews (Truman and Riddiford, 2002; Thummel, 2001 among others, as well as many chapters in this volume (see **Chapters 3.7** and **3.9**)) and the web specific information in Nurebase, a database specializing in nuclear receptors maintained in Lyon (Nurebase; Duarte *et al.*, 2002; Ruau *et al.*, 2004).

3.6.2. Nuclear Receptors in the Animal Kingdom

3.6.2.1. The Phylogeny of Nuclear Receptors

3.6.2.1.1. Classification of the nuclear receptors Molecular phylogeny has been applied to better delineate the evolutionary history of the nuclear

receptor superfamily (Amero *et al.*, 1992; Laudet *et al.*, 1992; Laudet, 1997; Thornton and DeSalle 2000; review: Escriva Garcia *et al.*, 2003). Since two main functional domains, the DBD and the LBD, are conserved in most nuclear receptors, phylogenetic trees have been produced using each of these domains alone or in combination. It is now clear that the DBD alone is too short and too conserved to contain a significant phylogenetic signal. Thus, if DBD-based trees contain accurate information on the grouping of closely related receptors (such as TRs and RARs) they are unable to correctly decipher deep relationships. Using the LBD alone provides a better resolution of the phylogeny but this is less robust than the phylogenies arising from the use of both DBD and LBD. Thus, despite several attempts it has been very difficult to compare the evolution of the DBD and the LBD using their phylogenies. The question of some degree of independence between the two domains during evolution is still open (see conflicting views in Escriva *et al.*, 2000 and Thornton and DeSalle, 2000). All the trees discussed in this review were constructed using both domains. It is important to note that several phylogenetic methods, namely maximum parsimony, distance analysis using neighbor-joining, or probabilistic approaches using maximum likelihood, have been used to produce nuclear receptor phylogeny. Despite some differences in specific regions of the trees (respective placement of ER, ERR, and steroid receptors, for example; Laudet, 1997; Thornton *et al.*, 2003), the topology of these trees and the conclusions that can be drawn from them are very similar. Thus, the phylogeny of the nuclear receptor superfamily is now relatively consensual and widely accepted.

Based on these results, the family has been divided into six subfamilies that are supported by high bootstrap values (**Figure 3**). It is worth noting that the relationships between these subfamilies are not supported and it is impossible to say which one is the most ancient, based only on sequence phylogeny.

1. The first subfamily contains several important liganded groups of nuclear receptors such as the thyroid hormone receptors (TRs), the retinoic acid receptors (RARs), the PPARs, the xenobiotic receptors PXR and CAR with their homolog in insect DHR96 (which is still considered an orphan receptor), the bile acid receptor FXR, the ecdysone receptor (ECR), and the oxysterol receptors (LXRs). In addition, this subfamily also contains two groups of orphan receptors, Rev-erb/E75 and ROR/HR3. It is interesting to note that ligands (namely cholesterol and retinoic acid) were recently proposed for the RAR-related orphan receptor (ROR) (Stehlin-Gaon *et al.*, 2003; Kallen *et al.*, 2002). The relationship between these groups is poorly resolved: if TR and RAR appear very often to cluster together with weak bootstrap values, such as for REV-ERB and ROR, the only clear and robust grouping joins LXR, FXR, and PXR groups.
2. The second subfamily clusters RXR, the 9-cis retinoic acid receptor, and its arthropod homolog USP that apparently does not bind this compound, and many groups of orphan receptors: TR2 and TR4 and their *Drosophila* homolog HR78, HNF4, the TLL group (with four genes in *Drosophila*: *TLL*, *DSF*, *PNR*, and *FAX1*), and the COUP-TF/SVP group. Of note is the presence of unusual receptors that contain only the LBD sequence, DAX and SHP clearly being members of this subfamily, probably related to TLL receptors (Laudet, 1997).
3. The third subfamily clusters steroid receptors (SRs), the estrogen receptor (ER), and the estrogen related receptors (ERRs) that are still orphan receptors. There is one ERR homolog in *Drosophila* but not for SRs and ERs. As their names indicate ERRs appear more closely related to ERs than to steroid receptors but this view has been challenged recently by data suggesting that ERs and SRs cluster together and are then joined by ERR. The respective placement of SRs, ERs, and ERRs is an important issue regarding ligand binding evolution and is still under discussion.
4. The fourth subfamily contains only the NGFIB group of orphan receptors with their unique arthropod homolog HR38.
5. The fifth subfamily contains the orphan receptor SF1 group, which contains a *Drosophila* homolog, FTZ-F1, as well as another gene, DHR39, whose origin is still unclear.
6. The last subfamily contains the orphan receptor GCNF with its ortholog in *Drosophila*, HR4.

It is important to note that the placement of three *Drosophila* genes that contain no LBD (KNI, KNRL, and EAGLE) is still unclear. They may be related to HR96 but, given the poor phylogenetic information present in the DBD sequences, it will be difficult to resolve their origin using phylogenetic analysis alone (Laudet, 1997).

Given the plethora of names available for the same sequence, it has proved useful to construct a nomenclature based on the nuclear receptor sequences using molecular phylogeny (Nuclear Receptor Nomenclature Committee, 1999). The system is based on the nomenclature system that was developed

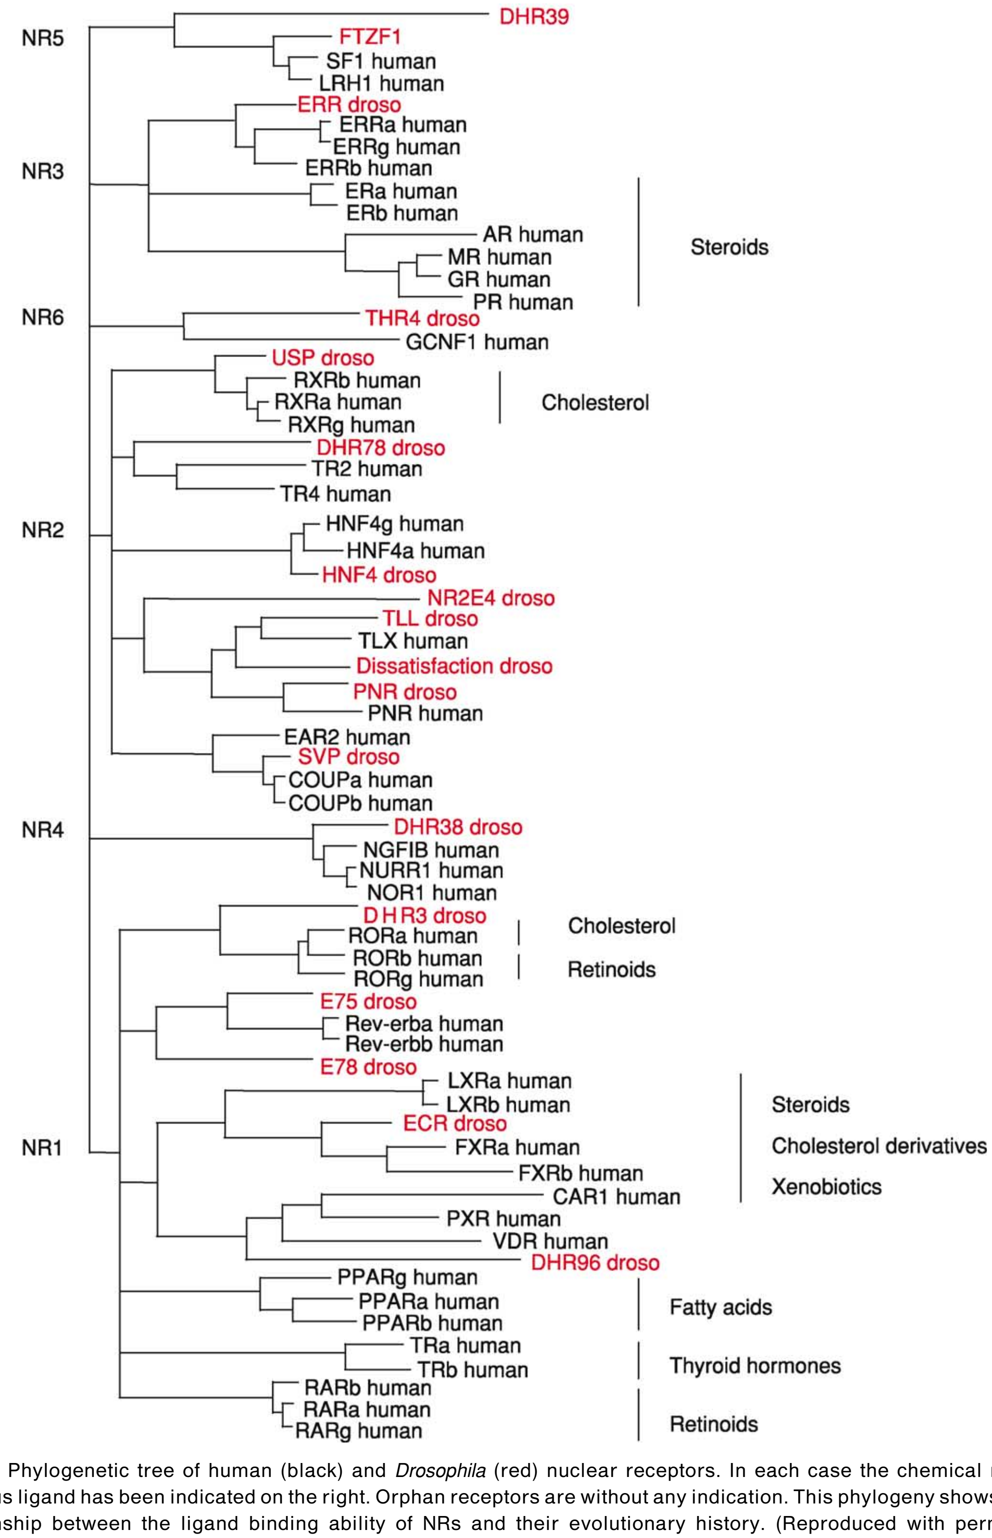

Figure 3 Phylogenetic tree of human (black) and *Drosophila* (red) nuclear receptors. In each case the chemical nature of the endogenous ligand has been indicated on the right. Orphan receptors are without any indication. This phylogeny shows that there is no relationship between the ligand binding ability of NRs and their evolutionary history. (Reproduced with permission from Robinson-Rechavi, unpublished data.)

for cytochrome P450. Each receptor is described by the letters NR (for "nuclear receptor") and a three-digit nomenclature: the subfamily to which a given receptor belongs is indicated by Arabic numbers, groups by capital letters, and individual genes by Arabic numbers. Thus, the *Drosophila* EcR that belongs to subfamily I, to group H in this subfamily, and which is the first gene described in that group

will be called NR1H1. The receptors that contain only one of the two functional domains (KNI group, DAX/SHP, and some nematode receptors such as Odr-7) are artificially clustered in subfamily 0. This system has proven to be flexible enough to integrate nuclear receptors from invertebrates as well as sequences generated from genome projects for which no pharmacological data are yet available. In order to follow the evolution of this nomenclature, the new names are available on a specific website (http://www.ens-lyon.fr/LBMC/laudet/nomenc.html) as well as on Nurebase.

3.6.2.1.2. Evolution of nuclear receptor functions It is always interesting to compare results from phylogenetic analysis with functional or morphological features of the group of sequences or organisms that are compared. For nuclear receptors, evolution of the superfamily with major functional characterizations of the receptors, namely DNA binding, dimerization abilities, and ligand binding (reviews: Escriva *et al*., 2000; Escriva *et al*., in press), is compared.

As discussed above, the vast majority of nuclear receptors recognize the core sequence RGGTCA organized either as DRs, inverted repeats (mostly palindromes), or alone with an upstream A/T-rich sequence. Nuclear receptors bind to these elements as homodimers, heterodimers, or monomers. In most cases, heterodimers are formed with RXRs (or USP in insects). When these functional characteristics are compared with the tree there is a very good correlation with the evolutionary history. For example, all members of subfamily II are able to form homodimers on direct repeat sequence, whereas all members of subfamily III can form homodimers on palindromic elements. Monomeric receptors able to bind unique RGGTCA sequences are found in many places on the tree (subfamilies I, IV, and V, for example). One of the most striking cases is the RXRs that are able to form heterodimers only with members of subfamilies I and IV. The only exception to the rule could be the case of COUP-TF and SVP, which have been described as being able to interact with RXRs (Kliewer *et al*., 1992; Cooney *et al*., 1993). Nevertheless, this finding is strongly debated and it is not clear whether this interaction represents a real heterodimer formation or could be viewed more as a classical protein–protein interaction (Butler and Parker, 1995). The only physiologically relevant data in favor of this interaction is the ECR-USP/SVP interaction found in *Aedes aegypti* (Miura *et al*., 2002; Zhu *et al*., 2003). It should be noted that the dimer interface of this complex has not been mapped and thus we cannot be sure that it represents a real heterodimer, such as RXR-TR. Despite this, it is clear that the DNA binding and dimerization abilities are reasonably well correlated with the evolutionary history, suggesting that the first nuclear receptor was able to bind the RGGTCA core sequence, most probably as a homodimer recognizing direct repeat sequences, and that subsequently there was divergence on this theme following the various gene duplications that gave rise to the present diversity of nuclear receptors.

A comparison of the phylogenetic tree with the ligand binding ability of the nuclear receptors reveals a very different picture. The following observations clearly suggest that the evolutionary relationships of nuclear receptors and the nature of their ligands are not correlated:

i. the presence of nuclear receptors for different ligands within subfamilies (e.g., TRs and RARs, which bind totally different compounds, are related inside subfamily I);
ii. closely related ligands recognized by different receptors (e.g., retinoids, which are ligands for RARs, RXRs, and RORβ); and
iii. the widespread distribution of orphan receptors in the phylogenetic tree.

This situation could be explained by an independent gain of ligand binding capacity during nuclear receptor evolution. This model implies that the first member of the nuclear receptor superfamily was an orphan receptor. In accordance with this notion, nuclear receptor sequences described from early metazoans are mostly orthologs of orphan receptors (Escriva Garcia *et al*., 1997, 2003; Grasso *et al*., 2001) with the notable exception of the RXR, whose endogenous ligand is still a matter of controversy (Kostrouch *et al*., 1998; Wiens *et al*., 2003). Although this model is not discussed in detail here, it is interesting to briefly mention some of its implications.

The C-terminal moiety of the nuclear receptor, which is called the ligand binding domain, is well conserved when compared across the whole superfamily, including orphan receptors for which structural data suggest an absence of ligand (e.g., NURR1; Wang *et al*., 2003). We know that the LBD carries a transcriptional activation domain that can be turned on by a conformational change that allows coactivator binding. It is clear that this conformational change can be induced not only by ligand binding but also by other mechanisms. For example, it is well known that phosphorylation events in the LBD can induce this conformational change (review: Weigel and Zhang, 1998). Alternatively, protein–protein interactions (such as the one occurring between SF1 and Ptx1 on two SF1

target genes), pituitary luteinizing hormone beta and Mullerian inhibiting substance may also induce coactivator binding (Tremblay *et al.*, 1999). Indeed, the Evans laboratory has suggested that the LBD exists in an equilibrium between an OFF and an ON conformation and that ligand binding directs this equilibrium in favor of the ON (holo) conformation (Schulman *et al.*, 1996). In conclusion, it is believed that ligand binding is only one of the possible switches and that this equilibrium can also be modified by phosphorylation or protein–protein interactions, among other mechanisms. Thus, it is suggested that the sequence conservation of the LBD is not the result of the conservation of ligand binding activity but is rather the hallmark of the existence of this conformational change in all nuclear receptors. The LBD should in fact be viewed as a domain responsible for an allosteric modification of the receptor allowing the exchange between corepressor and coactivator complexes. Seen in this perspective, it is not surprising that the LBD is conserved in orphan receptors.

Recent structural data have shed new light on the ligand binding ability of nuclear receptors. First, there is now substantial evidence that "real" orphan receptors (i.e., nuclear receptors that are not recognized by cognate endogenous ligands) may exist. This is the case for NURR1 and its *Drosophila* homolog HR38, which harbors a LBD folded in an active conformation but with a putative ligand binding pocket filled by large hydrophobic side chains, such that it is difficult to imagine a ligand occupying the same space (Baker *et al.*, 2003; Wang *et al.*, 2003). Other recent reports suggest that in some cases a structural "ligand" (e.g., fatty acid for *Drosophila* USP or for HNF4) may be present inside the LBD without playing any functional role (Billas *et al.*, 2001; Clayton *et al.*, 2001; Wisely *et al.*, 2002). In other cases (ERRγ and LRH-1), empty pockets are found in the nuclear receptor, which nevertheless has an active conformation that can be recognized by coactivators (Greschik *et al.*, 2002; Sablin *et al.*, 2003). Thus, the LBD of orphan nuclear receptors can contain pockets filled with side chain residues, pockets with structural ligands or empty pockets, demonstrating an unanticipated large number of possible states between receptors for well-known hormones and orphan receptors. This may render it difficult to define with precision endogenous ligands for a given receptor. Such a debate is currently raging about the RXR and its pharmacological ligand, 9-*cis* retinoic acid.

All these structural results may have evolutionary implications. It has been proposed that the first nuclear receptor had an exogenous molecule such as a fatty acid playing a structural role buried inside its LBD (Sladek, 2002). This compound cannot be called a ligand as it cannot regulate the activity of the receptor and cannot even exit the LBD. A receptor enclosing such a molecule could thus be considered as an orphan receptor such as the *Drosophila* USP. Second, some of these orphan receptors may have weakened the interaction between these structural ligands and the LBD and "invented" ligand regulated transcriptional activity (**Figure 4**). Although tempting, this model cannot be generalized and is not widely accepted at present, as recent structural data have shown that LBDs with an empty pocket or with no

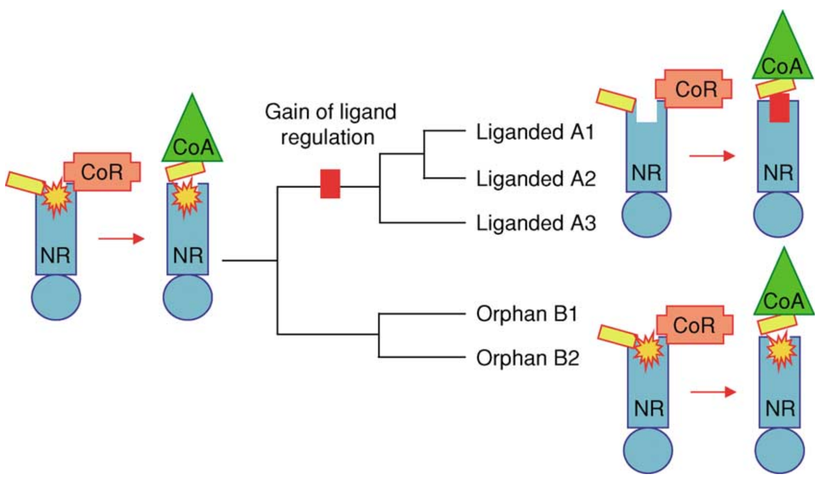

Figure 4 A possible scheme for the evolution of ligand binding abilities of nuclear receptors. The original nuclear receptor may have been able to bind a lipophilic compound that was a ''structural ligand,'' i.e., an integral component of the protein structure. In contrast, modern ligands are interchangeable elements that induce allosteric functional changes of the LBD. This model may explain why the LBD has been conserved during evolution. NR, nuclear receptor; CoR, corepressor; CoA, coactivator. Helix H12 is shown as a yellow box, the ligand as a red box, and the structural ligand as an irregular yellow form.

pocket are possible and apparently stable. The existence of "structural ligands" is thus perhaps less frequent than anticipated.

3.6.2.2. Metazoan Phylogeny and Nuclear Receptors: the Ecdysozoan Problem

3.6.2.2.1. Distribution of nuclear receptors in metazoans Recent molecular data have considerably refreshed our ideas and concepts on metazoan phylogeny (Aguinaldo *et al.*, 1997; de Rosa *et al.*, 1999). **Figure 5** depicts the present consensus on metazoan phylogeny. Although lively debates are ongoing on many aspects of this tree, several points should nevertheless be briefly discussed in relation to nuclear receptor evolution. The focus will be on the main metazoan phyla since for the vast majority of the 35 phyla no sequence information was available except some classical phylogenetic markers such as mitochondrial genes or ribosomal rRNA genes.

1. The identity of the unicellular eukaryote that is most closely related to metazoans has long been a mystery, but it is now clear that choanoflagellates, which share several cytological and molecular synapomorphies with metazoans, are the sister group of metazoans. Despite some ancient claims based on cross hybridization data or poor sequence identities, it is clear that nuclear receptors are not found outside the Metazoa. There is no known nuclear receptor homolog in the various plant or fungi genomes available and since more than a dozen such genomes are now available, the hypothesis of a secondary loss can be excluded. But this information is not sufficient to conclude that nuclear receptors are specific to metazoans. Indeed, nothing is known about the presence of nuclear receptors in choanoflagellates. Expressed sequence tag (EST) projects in choanoflagellates have not revealed nuclear receptors, but these genes are usually not frequent in these data because of a relatively low level of expression (King *et al.*, 2003). Indeed, the isolation of a nuclear receptor from the sister group of the Metazoa could illuminate our views on nuclear receptor origins, which remains obscure. Several reports have suggested low scores of sequence identity for the LBD and DBD regions of nuclear receptors with a peroxisomal membrane protein, Pex11p, and the LIM/GATA zinc finger domain, respectively. This has prompted some groups to suggest that the first nuclear receptor arose from the fusion of two genes encoding these various proteins (Clarke and Berg, 1998; Barnett *et al.*, 2000). In the absence of structural data that can confirm the significance of these low similarity scores, it is hard to draw firm conclusions on this matter. The question of the origin of the first nuclear receptor is thus still open.
2. The metazoans are monophyletic and sponges (Porifera) are clearly the first group that diverged from the metazoan trees. It is now believed that the sponges are not a monophyletic group and the precise phylogeny of the early metazoan tree is far from being resolved but the basal position of sponges when compared to cnidarians is widely accepted. Cnidarians (sea anemone, corals, *Hydra*) and other related groups such as the Ctenophora diverged later on.

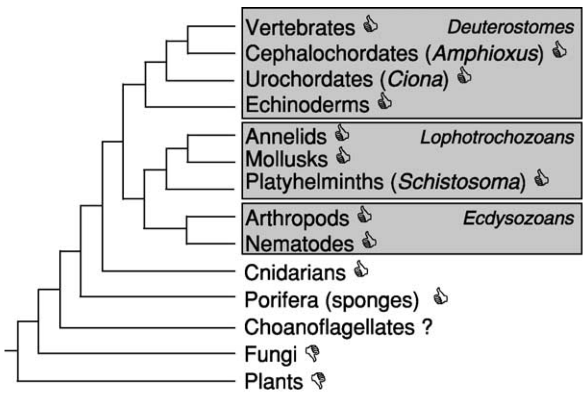

Figure 5 Simplified phylogeny of metazoans. Clades where NRs have been isolated are labeled with 👍, clades where complete genome sequences exist without any NR gene are labeled with 👎, and clades where the presence of NRs is not yet known are labeled with ? (Modified from Aguinaldo, A.M., Turbeville, J.M., Linford, L.S., Rivera, M.C., Garey, J.R., *et al.*, **1997**. Evidence for a clade of nematodes, arthropods and other moulting animals. *Nature 387*, 489–493; and Adoutte, A., Balavoine, G., Lartillot, N., de Rosa, R., **1999**. Animal evolution: the end of the intermediate taxa? *Trends Genet. 15*, 104–108.)

The presence of nuclear receptors in sponges has long been debated. In a polymerase chain reaction (PCR) screen, we found nuclear receptor signatures in all animal phyla analyzed from diploblastic animals (e.g., cnidarians; Escriva Garcia *et al.*, 1997) to vertebrates, but not in sponges. Recently, however, Werner Muller's group reported the presence of an RXR ortholog in the sponge *Suberites domuncula* (Wiens *et al.*, 2003). Even if the precise identity of this receptor is unclear, it is undoubtedly a member of subfamily II that currently contains, to the exclusion of the RXR, only orphan receptors and which appears to be the most ancient one.

The ancestry of subfamily II has been clearly established in our PCR screen that yields subfamily II homologs (COUP-TF, RXR) together with a subfamily V homolog (FTZ-F1) in *Hydra* and *Anemonia*, two cnidarians (Escriva Garcia *et al.*,

1997). This has been confirmed by the isolation of several nuclear receptors (RXR (NR2B), TR2/4 (NR2C), TLL (NR2E), COUP-TF (NR2F)) in various cnidarians such as *Montipora verrucosa, Tripedalia cystophora*, and *Acropora millepora* (Kostrouch *et al*., 1998; Grasso *et al*., 2001). Of note, is the presence of subfamily V members in cnidarians, which has not been confirmed by independent evidence and should thus be regarded as tentative. Thus, only subfamily II is clearly present in all metazoans, suggesting that the first nuclear receptor and thus the origin of the superfamily probably belonged to this subfamily.

3. The bilaterians, metazoans that possess three embryonic layers and bilateral symmetry, are split in two main groups, the protostomians and deuterostomians, which differ on many morphological and molecular characters. Interestingly, all bilaterians are now included in one of these two groups. Protostomians are split into two stable groups: the ecdysozoans (animals that molt) including arthropods and nematodes; and the lophotrochozoans including mollusks, annelids, and flatworms (Aguinaldo *et al*., 1997). Several complete genomes of members of the Ecdysozoa are available (*Caenorhabditis elegans, Caenorhabditis briggsae, Drosophila melanogaster, Anopheles gambiae*), while the lophotrochozoans are a genomic desert with very few data available and no complete genome sequence available as yet. Thus, many surprises are expected to come from the molecular and comparative genomic study of this group.

Indeed, the comprehensive phylogenetic analysis of all nuclear receptors found in complete genome sequences, as well as the identification of an ER ortholog in a mollusk, strongly suggest that liganded receptors such as TRs, RARs, or SRs that were believed to be specific to the vertebrate lineage are probably more widespread among metazoan animals than previously thought (Thornton *et al*., 2003; Bertrand *et al*., in press). Importantly, analysis of the complete nuclear receptor set in a given genome allows one to establish unambiguously whether this genome has lost some nuclear receptor if these genes are present in other metazoan species. For example, the fact that *Drosophila, C. elegans*, and *Ciona* genomes do not harbor an ER may be viewed as an argument in favor of the fact that ERs are found only in recent chordates, even if the topology of the tree indicates an ancestry of ER in bilaterians. But the recent cloning of a clear ER ortholog in a mollusk (even if this receptor apparently does not bind estrogens!) permits reconciliation of the tree topology with the model and leads to the suggestion that indeed an ER ortholog was present in the common ancestor of all bilaterians and was lost independently in nematodes and the *Drosophila* genomes as well as in *Ciona*. This example illustrates very clearly the derived nature of the *Drosophila* and nematode genomes and the importance of lophotrochozoan analysis. Thus, the search for nuclear receptor genes in lophotrochozoans is clearly a priority for future research.

The analysis of all nuclear receptors present in bilaterians allows us to propose the basic set of nuclear receptors in metazoan phyla. The principle of this inference is that for each group of nuclear receptors we can locate the speciation event that led to the deuterostome and protostome lineages by the divergence between chordate, insect, and nematode orthologs. Then all genes resulting from duplications, which occurred before this speciation, were probably present in Urbilateria. Using this reasoning, which remains correct even if secondary loss occurred in some lineages, it appears that the genome of the common ancestor to nematodes, insects, and chordates had at least 25 nuclear receptor genes (Bertrand *et al*., in press). Any variation from this number should be explained by lineage specific events such as gene loss (i.e., arthropods and nematodes) or gene duplications that arose often in certain lineages (i.e., vertebrates or nematodes).

3.6.2.2.2. Nuclear receptors, nematodes, and the ecdysozoan The case of ecdysozoans is of course particularly relevant for the analysis of nuclear receptor evolution in arthropods. Nematodes, arthropods, and other phyla such as onychophorans are grouped in the Ecdysozoa, animals that share the developmental trait of molting, although this grouping is still debated (Aguinaldo *et al*., 1997; Blair *et al*., 2002). Genomic data reveal that nematodes contain a very large number of nuclear receptor genes (up to 270) whereas insects (*Drosophila* and *Anopheles*) harbor 21 nuclear receptor genes. Three questions are relevant for nuclear receptor evolution in ecdysozoans: (1) what was the extent of gene loss events that occurred during ecdysozoan evolution; (2) in this context, by what mechanisms did nematodes reach such an impressive number of nuclear receptors and did gene duplication play any role in nuclear receptor evolution in arthropods; and (3) are nuclear receptors linked to the grouping of ecdysozoans and their molting behavior?

As discussed above, the common ancestor of all bilaterians probably had 25 nuclear receptor genes in its genome. Since Diptera genomes contain 21

genes, a simple conclusion could be that arthropods lost four genes. In fact, the phylogenetic analysis of the nuclear receptors of bilaterians reveals a much more complex and interesting picture (Bertrand *et al.*, in press). Both *Drosophila* and nematode genomes lost several genes such as TR, RAR, PPAR, ER, SR, EAR2, and LXR. Whether these genes have been lost only once in the common ancestor of *Drosophila* and nematodes (i.e., the ancestor of all Ecdysozoa) or twice independently in these two lineages remains unclear. We will need information on other ecdysozoans to resolve this issue. In addition, it is clear that nematodes (or at least *C. elegans*) lost other genes such as *HR39, ERR, RXR, TLL, DSF, PNR, EcR*, and *E75*. It is possible that some of these genes still exist in nematode genomes but that their assignation is obscured by strong sequence divergence since nematode nuclear receptors genes, like many other genes, evolved rapidly (Robinson-Rechavi *et al.*, unpublished data).

It is of course very interesting to see that the analysis of dipteran genomes in the context of other bilaterians reveals the loss of seven nuclear receptor genes among which six are encoded liganded receptors. It is important to note, however, that this conclusion is reached only by the analysis of the nuclear receptor set present in the *Drosophila* and *Anopheles* complete genomes. There is a long road from the common ancestor of Ecdysozoa to the common ancestor of Diptera and it is not absolutely clear when these losses occurred and whether they occurred simultaneously. Thus, we can expect that some of these genes will be found in some ecdysozoans and even in some arthropods or primitive insects. Since many researchers working on arthropods have been influenced by the set of nuclear receptors present in *Drosophila*, it came as no surprise that for example SR, ER, or PPARs were not searched for in more primitive insects or arthropods. These data would allow us to revise the nuclear receptor set present in Ecdysozoa. Another basic question suggested by this analysis is why arthropods lost so many liganded receptors and what are the remnants of these signaling pathways still present in the genome of these organisms. This will be the subject of future analysis.

Returning to the premise that the urbilateria genome probably had 25 nuclear receptors, of which seven were lost in Ecdysozoa leading to 18 nuclear receptor genes, we then find that dipteran genomes contain 21 nuclear receptor genes. Interestingly, the three supplementary receptors are the three highly unusual members of the KNI group (knirps, knirps-related, and eagle) that clearly form a group of relatively recent duplicates. In nematodes, the situation is much more striking since the nematode genome lost more genes ($7+8=15$) but contains more than 270 receptors. The phylogenetic analysis of nematode nuclear receptors led to show that the *C. elegans* genome contains 13 ancient nuclear receptors and approximately 250 supplementary receptors that are the result of an explosive diversification of a unique gene, HNF4. In fact, it can be concluded that *C. elegans* as well as *C. briggsae* and probably others contain approximately 250 HNF4 genes! These genes are highly divergent and not functionally or structurally linked and the reason for such a massive increase in gene number is still far from being clear (Robinson-Rechavi *et al.*, unpublished data). Nevertheless, it should be emphasized that examples of lineage specific expansion in gene number are found for other types of genes and in other genomes suggesting that this is an event more widespread than expected.

In the perspective of nuclear receptor evolution, it is fundamental to recall, given the important role played by EcR and several other nuclear receptors, that the ecdysozoan group is composed of animals that molt. In this context, it is tempting to speculate that the ecdysone signaling cascade, including the EcR-USP heterodimer would be an obvious ecdysozoan synapomorphy (de Mendonca *et al.*, 1999). It is thus striking, and even irritating, to find neither an ecdysone receptor nor an RXR in the *C. elegans* genome. Did molting evolve several times independently in Ecdysozoa? The lack of resolution of this issue illustrates once again that we should be very cautious in the conclusions that we draw from classical model organisms such as *C. elegans* or *Drosophila*. Indeed, if *C. elegans* effectively lacks EcR and USP homologs, this unexpected property is not widespread in nematodes. *Dirofilaria immitis*, a parasitic nematode, does contain an ortholog of EcR and USP (Shea *et al.*, 2003). Thus, before concluding that a given receptor is absent in a large zoological group such as nematodes one should always also look at data from several species not too closely related. Unfortunately, this striking situation also suggests that *C. elegans* will be a poor model for comparing events governing molting in nematodes with the same events in arthropods.

The other question related to the ecdysozoan issue is whether the molting and EcR-USP signaling cascades are widespread outside the Ecdysozoa. If the answer is yes, then this no longer can be viewed as an ecdysozoan synapomorphy. The lack of resolution of this question underlines the profound ignorance of molecular mechanisms regulating the development in protostomians (besides *C. elegans* and *D. melanogaster*) in general and in lophotrochozoans in

particular. Ecdysteroids have been described in *Schistosoma* but the significance of this observation is far from clear (de Mendonça *et al.*, 2000a). To date, no EcR ortholog has been found in *Schistosoma*, which is an interesting observation given that a very large number of EST sequences, including many nuclear receptors, are available in this species (Verjovski-Almeida *et al.*, 2003). Thus, with our present, very limited knowledge, the proposal that EcR-USP signaling represents an ecdysozoan synapomorphy, although probably oversimplistic, is still acceptable.

3.6.3. Phylogeny of Nuclear Receptors in Arthropods

3.6.3.1. Towards an Inventory

Despite their functional importance, the evolution of arthropod nuclear receptors has been largely overlooked (Henrich and Brown, 1995). Three reasons may account for this disappointing situation. First, the sequencing effort has focused mainly on Diptera (*Drosophila*, malaria vector *An. gambiae*, yellow fever mosquito *Ae. aegypti*) and Lepidoptera (silk worm *B. mori*, tobacco hornworm *M. sexta*), which are two closely related and highly derived holometabolous orders of insects. Therefore, the sample of available sequences is small and evolutionarily incomplete (Figure 6). Second, these proteins have not been studied in insects as a homogeneous family of transcription factors, such as the products of *Hox* genes for example. Rather, they were analyzed separately through their involvement in various developmental pathways, like embryonic segmentation (*knirps*, *tailless*, *Ftz-F1*), molting and metamorphosis (*EcR*, *Usp*, *Ftz-F1*, *E75*...), or eye morphogenesis (*seven-up*). However, their common structure and mode of action requires an integrated view of their evolution. Third, to the exclusion of EcR, ligands still remain to be identified for the nuclear receptors of arthropods. Whether they are all real orphans or not is still an open question and an essential issue is to understand their function and their evolution. Nevertheless, we can draw here a summary of the present knowledge, in order to suggest the orientations of the future work that should help to understand both the evolution of nuclear receptors and their role during diversification of insects and other arthropods.

All the arthropod nuclear receptors known to date can be classified into the seven subfamilies previously described (Figure 1) (Laudet, 1997). For many of them it is easy to identify a sequence relationship with a chordate receptor. However, it appears that rapid evolutionary divergence produced nuclear

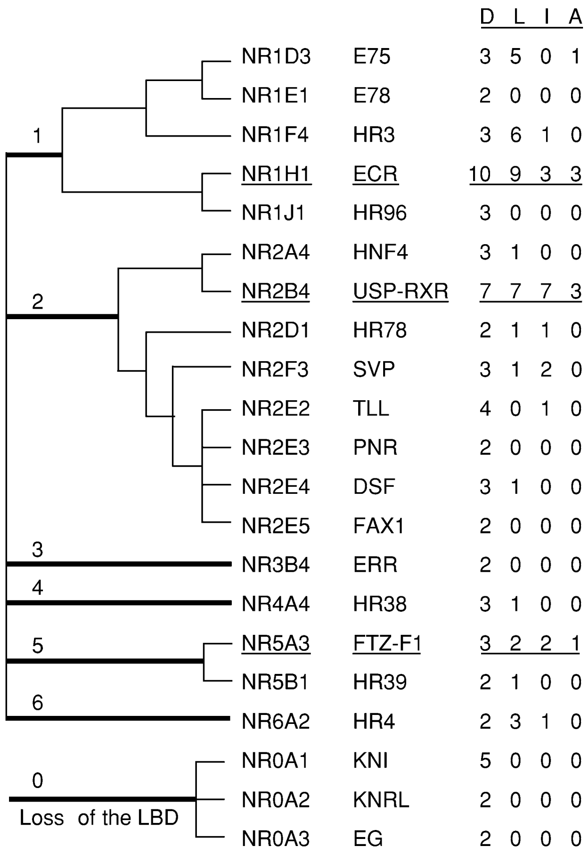

Figure 6 Phylogeny of identified nuclear receptors in arthropods. The schematic unrooted tree of the six subfamilies is a simplified version of that from the Nuclear Receptors Nomenclature Committee (1999). In addition, the NR0 subfamily is shown at the bottom of the figure. Branches in bold are those leading to a subfamily with the corresponding number written above the branch. Two names are given for each nuclear receptor: on the left is the official nomenclature and on the right is the trivial name used in this chapter. The number of species where one given receptor has been identified (update: July 2003) is also indicated. Four groups of species have been defined: D, Diptera; L, Lepidoptera; I, other insects; and A, other arthropods (Bonneton *et al.*, 2003). When a nuclear receptor is found in all of these four groups, its name is underlined.

receptors that may be specific to insects or other arthropods. Because ECR and USP-RXR show such a divergence and have been intensively studied (see **Chapter 3.5**), their evolution will be considered separately.

3.6.3.1.1. Subfamily 1: all members of the ecdysone pathway In insects, subfamily NR1 contains five receptors, which are all directly involved in the ecdysone pathway of *D. melanogaster* (Figure 7). They can be separated into two distinct groups, based on structural as well as functional data (Laudet, 1997; Thornton and Desalle, 2000). The first group includes E75 (NR1D3), E78 (NR1E1), and HR3 (NR1F4). All of their vertebrate homologs

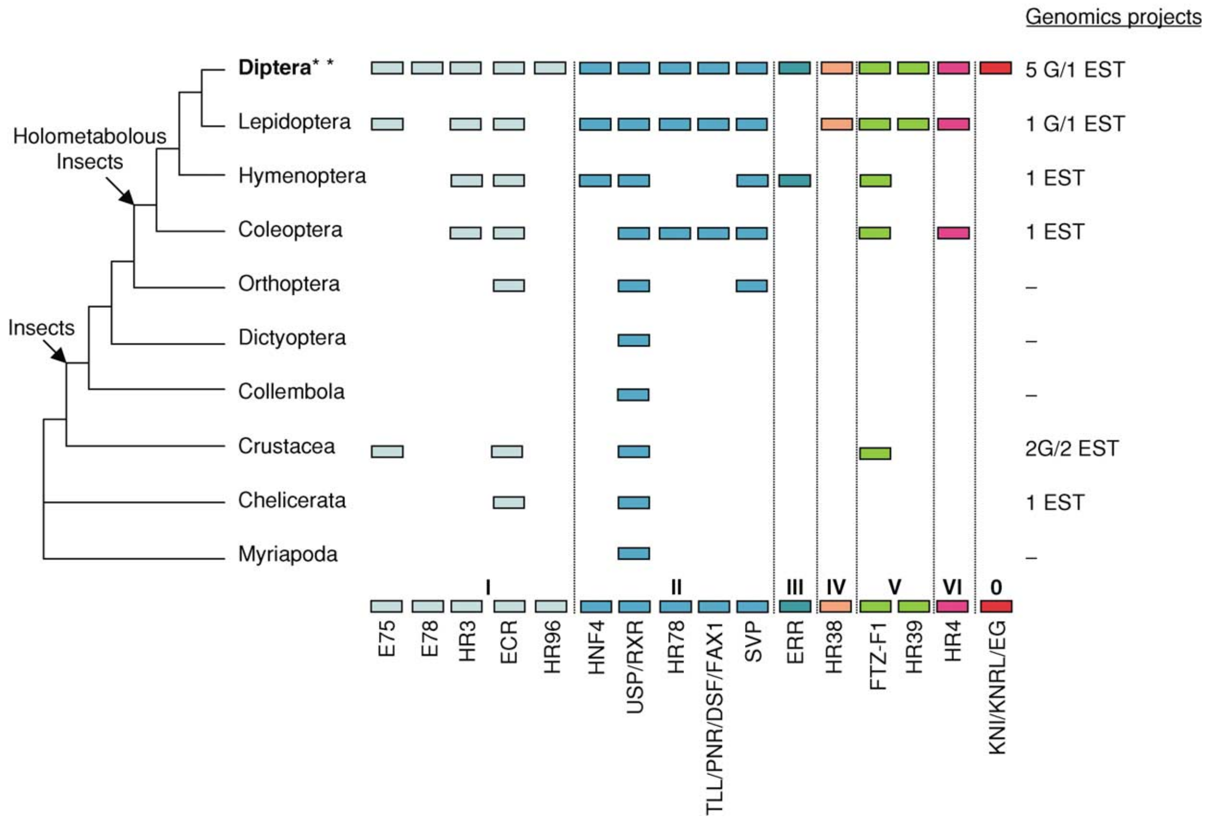

Figure 7 Phylogenetic distribution of identified nuclear receptors in arthropods. On the left, a tree indicates the evolutionary relationships between the groups where nuclear receptors are known (Kristensen, 1981; Whiting *et al.*, 1997; Hwang *et al.*, 2001; Giribet *et al.*, 2001). Diptera is written in bold with two asterisks (*) to highlight the fact that two complete genome sequences are available for this order (*D. melanogaster* and *An. gambiae*), allowing for an accurate account of nuclear receptors (Bertrand *et al.*, in press). Concerning Hymenoptera, we have found HR3, HNF4, SVP, and ERR in *Apis* ESTs. The 16 groups of arthropod nuclear receptors are indicated by rectangular boxes colored according to their subfamilies, which are shown at the bottom of the figure (subfamilies 0, I, II, III, IV, V, VI). The ongoing complete genome (G) and EST sequencing projects are listed on the right (GOLD); –, no known project.

are orphan receptors that are unable to form heterodimers with RXR. The second group contains the famous ecdysone receptor, EcR (NR1H1), and the less well-known HR96 (NR1J1). Both proteins may be specific to Ecdysozoa. Note that several nuclear receptors of subfamily 1 found in chordates have no homologs in arthropods and nematodes: thyroid hormone receptors (TRs, NR1A), retinoic acid receptors (RARs, NR1B), and peroxisome proliferator-activated receptors (PPAR, NR1C) that bind fatty acids (Laudet and Gronemeyer, 2002). In fact, a recent analysis of data provided by genomic projects suggests that this group of "classical" hormone receptors may be very ancient (present in the ancestor of bilateria) and was lost in ecdysozoans (Bertrand *et al.*, in press).

3.6.3.1.1.1. E75 The E75 gene (*Eip75B* in the FlyBase, NR1D3) has been identified in *D. melanogaster* (Feigl *et al.*, 1989; Segraves and Hogness, 1990), *An. gambiae* (Bertrand *et al.*, in press), *Ae. aegypti* (Pierceall *et al.*, 1999), and several species of Lepidoptera (Segraves and Woldin, 1993; Jindra *et al.*, 1994a; Palli *et al.*, 1995; Palli *et al.*, 1997b; Zhou *et al.*, 1998; Swevers *et al.*, 2002). It was also isolated from the shrimp *Metapeneus ensis* (Chan, 1998). These proteins are homologous to the vertebrate receptors REVERB-α and REVERB-β, which have been shown to be constitutive transcriptional repressors involved in the pacemaker controlling the circadian clock in vertebrates (Preitner *et al.*, 2002) (see **Chapter 4.11**). In insects, E75 acts as a repressor of HR3, probably through direct interaction, both in *Drosophila* (White *et al.*, 1997) and in *Bombyx* (Swevers *et al.*, 2002). The possible implication of E75 in circadian rhythmicity is still not known (see **Chapter 4.11**). In *Drosophila*, inactivation of all E75 functions causes first instar larval lethality, but isoform specific null mutations reveal different functions for each of the three isoforms (Bialecki *et al.*, 2002). The complex role of this gene is far from being fully understood but expression

and hormonal induction data suggest that its involvement in early ecdysone responses during molting and metamorphosis may be shared among arthropods (Jindra *et al.*, 1994a; Palli *et al.*, 1997b; Chan, 1998; Zhou *et al.*, 1998). It also plays a role during oogenesis and vitellogenesis in *Drosophila* (Bryant *et al.*, 1999), *Aedes* (Pierceall *et al.*, 1999; Raikhel *et al.*, 2002) (see **Chapter 3.9**), and *Bombyx* (Swevers *et al.*, 2002).

3.6.3.1.1.2. E78 The E78 gene (*Eip78C* in the FlyBase, NR1E1) is only known in Diptera (*Drosophila* and *Anopheles*) and although it is related to E75 and REVERB, it is extremely divergent from both of them. It could be a paralog of E75 that experienced a rapid evolutionary rate. Interestingly, the same situation is observed in nematodes, with the presence of an ortholog of E75 (nhr-85 in *C. elegans*) together with an ortholog of E78 (SEX-1 in *C. elegans*) (Kostrouch *et al.*, 1995; Carmi *et al.*, 1998; Unnasch *et al.*, 1999; Sluder and Maina, 2001; Crossgrove *et al.*, 2002). It is therefore possible that, in addition to one NR1D gene related to REVERB, all ecdysozoans also possess one specific fast-evolving NR1E gene that has been lost in chordates (Bertrand *et al.*, in press). However, mutant phenotypes indicate that this NR1E gene probably plays different roles in insects and in nematodes. Indeed, in *Drosophila*, E78 homozygous mutants are viable and fertile, with subtle defects in regulation of some puffs and in formation of dorsal chorionic appendages (Russel *et al.*, 1996; Bryant *et al.*, 1999). By contrast, the E78 ortholog (SEX-1) of *Caenorhabditis* is required for sex determination and viability of hermaphrodites (Carmi *et al.*, 1998).

3.6.3.1.1.3. HR3 Orthologs of HR3 (*Hr46* in FlyBase, NR1F4) have been identified in Diptera (Koelle *et al.*, 1992; Kapitskaya *et al.*, 2000; Bertrand *et al.*, in press) and Lepidoptera (Palli *et al.*, 1992; Jindra *et al.*, 1994b; Palli *et al.*, 1995, 1996; Matsuoka and Fujiwara, 2000; Debernard *et al.*, 2001), and a short sequence (partial DBD) is also available from the coleopteran *Tenebrio molitor* (Mouillet *et al.*, 1999). This receptor is well conserved outside insects, with one gene in *Caenorhabditis* (Kostrouch *et al.*, 1995) and three homologs in vertebrates: ROR α, β, γ, which are transcriptional activators (Jetten *et al.*, 2001). It has been shown recently that cholesterol and all-trans retinoic acid are ligands for RORα (Kallen *et al.*, 2002) and RORβ (Stehlin-Gaon *et al.*, 2003), respectively. RORs and REVERB bind to the same response element and RORs are thought to be competitors for REVERB. As such, they are believed to play an important role in circadian rhythm (Andre *et al.*, 1998). HR3 is an ecdysone inducible early–late gene that plays a key role during *Drosophila* metamorphosis by repressing early genes and directly inducing the prepupal regulator FTZ-F1 (Lam *et al.*, 1997; White *et al.*, 1997). This function in molting and metamorphosis is probably conserved throughout insects, as suggested by studies of expression and hormonal induction in *Manduca* (Palli *et al.*, 1992; Lan *et al.*, 1997, 1999; Langelan *et al.*, 2000), *Choristoneura fumiferana* (Palli *et al.*, 1996, 1997a), and *Tenebrio* (Mouillet *et al.*, 1999). Interestingly, inhibition of HR3 expression using RNAi showed that this gene is also required for *Caenorhabditis* molting, suggesting a conserved role in Ecdysozoa (Kostrouchova *et al.*, 1998, 2001). As for E75, HR3 is a functionally complex gene involved in many aspects of the ecdysone pathway. For example, a role in oogenesis and vitellogenesis has been described for *Aedes* (Kapitskaya *et al.*, 2000; Li *et al.*, 2000; Raikhel *et al.*, 2002) (see **Chapter 3.9**), *Bombyx* (Eystathioy *et al.*, 2001), and *Caenorhabditis* (Kostrouchova *et al.*, 1998). HR3 is also expressed in embryos of *Drosophila* (Carney *et al.*, 1997) and *Caenorhabditis* (Kostrouchova *et al.*, 1998). Furthermore, *Drosophila* HR3 mutants have defects in their nervous system and die during embryogenesis (Carney *et al.*, 1997). Given the wide variety of tissues and stages of expression for HR3, it is clear that other functions will be identified by detailed analysis of mutants. This is nicely illustrated by two studies showing a specific role for HR3 during the formation of wings in *Drosophila* and in *Bombyx*. Clonal analysis reveals requirements for *Drosophila* HR3 in the development of adult wings, bristles, and cuticle, but no apparent function in eye or leg development (Lam *et al.*, 1999). In a *Bombyx* wing deficient mutant called *flügellos*, HR3 expression is reduced only in wing discs, and not in the testis and fat body, while ECR, USP, E75, and HR38 are not affected (Matsuoka and Fujiwara, 2000). The wings are one of many organs where HR3 is expressed, and the role of this gene in their development in two different insects could only be revealed with appropriate genetic manipulations.

3.6.3.1.1.4. HR96 The HR96 (NR1J1) gene has been identified in *Drosophila* (Fisk and Thummel, 1995) and in *Anopheles* (Bertrand *et al.*, in press). In *Caenorhabditis*, three homologs are known: DAF-12, NHR-8, and NHR-48 (Sluder and Maina, 2001). All these ecdysozoan receptors are related to the vertebrate receptors NR1I: VDR, which is the receptor for vitamin D, PXR and CAR, which both bind a wide variety of xenobiotics (Laudet, 1997). Given the fact that the vertebrate homologs of

HR96 bind steroid-derived compounds, it is likely that HR96 also binds such a ligand. Since ECR and its vertebrate homologs LXR and FXR can bind steroids, it is even tempting to speculate that all the related nuclear receptors NR1H/J have the same property. It is also possible that HR96 requires USP-RXR to bind DNA in the same way as the other NR1H/I/J receptors. Little is known about the functions of HR96, which is inducible by 20E and is expressed during the onset of metamorphosis (Fisk and Thummel, 1995). The *Caenorhabditis* homologous gene *daf-12*, which functions downstream of the insulin and TGF-β signaling pathways, regulates diapause, developmental age, and adult longevity (Antebi *et al*., 1998, 2000; Gerisch *et al*., 2001; Jia *et al*., 2002). Interestingly, a growing number of studies suggest that common regulatory mechanisms control developmental timing in *Caenorhabditis* and *Drosophila*, with a central role for the ecdysone pathway in insects (Thummel, 2001) (see **Chapters 3.3** and **3.5**).

3.6.3.1.2. Subfamily 2: a large collection of old and new genes Only subfamilies NR2 and NR5 have been found in all metazoans, suggesting that they are probably at the origin of the superfamily (Escriva *et al*., in press). Most of the NR2 proteins are orphans (except HNF4 and RXR) and do not form heterodimers (except USP-RXR). In insects, subfamily NR2 contains eight genes, including the most conserved nuclear receptors: HNF4, seven-up (SVP-COUP), and tailless (TLL). The tailless group (NR2E) contains four different genes that exhibit a rather restricted pattern of expression: TLL, PNR, DSF, and FAX1. Probably they all share a primary function in the developing nervous system (see **Chapter 2.4**).

3.6.3.1.2.1. HNF4 HNF4 (NR2A) is one of the best-conserved nuclear receptors between arthropods and vertebrates. This gene was identified in *Drosophila* (Zhong *et al*., 1993), *Aedes* (Kapitskaya *et al*., 1998), *Anopheles* (Bertrand *et al*., in press), and *Bombyx* (Swevers and Iatrou, 1998). Two homologous HNF4 genes exist in mammals. In *Caenorhabditis*, a surprising explosive burst of duplications of HNF4 produced most of the (>270) supplementary nuclear receptors found in this species (Robinson-Rechavi *et al*., unpublished data). The embryonic expression pattern of this receptor is remarkably well conserved between insects and vertebrates. Indeed, HNF4 is transcribed zygotically in several analogous organs: the midgut, Malpighian tubules, and fat body of insects (Zhong *et al*., 1993; Kapitskaya *et al*., 1998; Swevers and Iatrou, 1998) and the intestine, kidney, and liver of vertebrates (Laudet and Gronemeyer, 2002). Furthermore, analyses of mutants show that the development of these organs requires HNF4 activity in *Drosophila* (Zhong *et al*., 1993) as well as in the mouse (Chen *et al*., 1994). If conflicting results were obtained concerning the role of HNF4 in the fat body of *Drosophila* embryos (Zhong *et al*., 1993; Hoshizaki *et al*., 1994), this gene is clearly transcribed in the fat body of *Aedes* adults (Kapitskaya *et al*., 1998) as well as in the *Bombyx* larvae and pupae (Swevers and Iatrou, 1998). In the mosquito, three isoforms have been identified, each having a specific temporal pattern during the vitellogenesis that takes place in the female fat body (Kapitskaya *et al*., 1998). Therefore, HNF4 probably performs similar functions during the formation of the gut and its derivatives in a large range of metazoans. Another conserved pattern is the maternal expression of HNF4, but its function has not been studied. It has been shown recently that the mammalian HNF4 receptor binds fatty acids constitutively (Dhe-Paganon *et al*., 2002; Wisely *et al*., 2002). Given the strong similarity (85%) observed for the HNF4 LBD between insects and vertebrates, it is tempting to speculate that this type of ligand may also be used in insects.

3.6.3.1.2.2. HR78 The HR78 gene (NR2D1) has been identified in *Drosophila* (Fisk and Thummel, 1995; Zelhof *et al*., 1995b), *Anopheles* (Bertrand *et al*., in press), *Bombyx* (Hirai *et al*., 2002), and *Tenebrio* (Mouillet *et al*., 1999). These genes are distantly related to the vertebrate's orphan receptors TR2 and TR4, and to the very divergent nematode genes *nhr-41* (*Caenorhabditis*; Sluder and Maina, 2001) and *nhr-2* (filarial nematode *Brugia malayi*; Moore and Devaney, 1999). As with most of the early genes of the ecdysone cascade (including ECR, E75, and E78), the developmental expression of HR78 is globally stable between the species of the *D. melanogaster* subgroup (Rifkin *et al*., 2003). HR78 is required for ecdysteroid signaling during the onset of metamorphosis of *Drosophila* (Fisk and Thummel, 1995; Zelhof *et al*., 1995b; Fisk and Thummel, 1998). This receptor is inducible by 20E and binds to over 100 sites on polytene chromosomes, many of which correspond to ecdysteroid regulated puff loci. By contrast with the important sequence divergence of the proteins, the temporal profile of expression of HR78 is very well conserved between *Drosophila* and *Tenebrio*, with an early activation at the end of larval stages, followed by a rather constant level during prepupal stages (Fisk

and Thummel, 1995; Zelhof *et al*., 1995b; Mouillet *et al*., 1999). *Drosophila* HR78 null mutants die during the second and third larval instar with tracheal defects, showing that, despite a uniform expression in the embryo, this receptor is not essential for early development (Fisk and Thummel, 1998; Astle *et al*., 2003). A surprising result was obtained by studying the *Bombyx* homolog. Indeed, yeast two hybrid and pull down assays showed that *Bombyx* HR78 could interact with USP-RXR (Hirai *et al*., 2002). If we consider that HR78 and ECR bind to the same DNA sites (Fisk and Thummel, 1995; Zelhof *et al*., 1995b), and have the same USP-RXR partner, it is therefore possible that competition occurs between these two proteins during the onset of metamorphosis.

3.6.3.1.2.3. SVP The *seven-up* gene (SVP, NR2F3) is a member of the COUP-TFs group, the most conserved nuclear receptors. It has been identified in various insects: *Drosophila* (Henrich *et al*., 1990; Mlodzik *et al*., 1990), *Aedes* (Miura *et al*., 2002), *Bombyx* (Togawa *et al*., 2001), and partial clones were also recovered from *Tenebrio* (Mouillet *et al*., 1999) and the grasshopper *Schistocerca gregaria* (Broadus and Doe, 1995). One homolog was studied in *Caenorhabditis* (Zhou and Walthall, 1998), and three COUP-TF genes are present in vertebrates (Pereira *et al*., 2000). These orphan receptors have a very broad pattern of expression and are essential for development in all the organisms studied. In the embryos of *Drosophila* and *Schistocerca*, SVP was found in the developing eyes, the central and peripheral nervous systems, the Malpighian tubules, and the fat body (Mlodzik *et al*., 1990; Hoshikazi *et al*., 1994; Broadus and Doe, 1995; Kerber *et al*., 1998; Sudarsan *et al*., 2002). Analysis of mutants demonstrated the functional role of these expressions in *Drosophila*. In addition, SVP participates in the diversification of cardioblasts in the heart tube of *Drosophila* embryos (Lo and Frasch, 2001; Ponzielli *et al*., 2002). The SVP protein is regulated by different pathways, such as Ras in eyes, EGF in Malpighian tubules, and hedgehog in heart, and thus plays multiple roles from cell fate determination to regulation of cell cycle and differentiation. Interestingly, SVP/COUP-TF inhibits USP-RXR signaling pathways, both in vertebrates and in insects. This has been tested *in vivo* with *Drosophila* in which the overexpression of SVP that leads to lethality at the onset of metamorphosis can be rescued by a concomitant overexpression of USP-RXR (Zelhof *et al*., 1995a). It is of note that SVP is expressed at the beginning of metamorphosis, when the ecdysteroid titer is low, both in *Drosophila* and in *Tenebrio* (Mouillet *et al*., 1999). A similar inhibition of 20E response occurs during vitellogenesis in the mosquito *Aedes* (see **Chapter 3.9**). Furthermore, in this species, it was shown *in vitro* that the repression of the ecdysone pathway is probably due to a direct interaction between SVP and USP-RXR. The replacement of ECR by SVP in USP-RXR heterodimers would be essential for the termination of vitellogenesis, when the ecdysteroid titer declines (Miura *et al*., 2002; Zhu *et al*., 2003). However, it must be noted that no physical interaction between SVP and USP-RXR was detected in *Drosophila* (Zelhof *et al*., 1995a).

3.6.3.1.2.4. TLL The *tailless* gene (TLL, NR2E2) is one of the most conserved nuclear receptors. It was first identified in *Drosophila* as a terminal gap gene determining embryo segmentation (Jürgens *et al*., 1984). Homologs have been studied in *Drosophila virilis* (Liaw and Lengyel, 1993), the house fly *Musca domestica* (Sommer and Tautz, 1991), and the coleopteran *Tribolium castaneum* (Schröder *et al*., 2000). Nematodes and vertebrates also have one *tailless* gene. The early terminal expression is necessary for the establishment of the nonmetameric domains at the anterior and posterior poles of the *Drosophila* embryo (Jürgens *et al*., 1984; Pignoni *et al*., 1990). This pattern is very well conserved in Diptera (Sommer and Tautz, 1991; Liaw and Lengyel, 1993). By contrast, the early posterior expression of *tailless* in *Tribolium* reveals a temporal divergence. This difference suggests that tailless may not function as a gap gene in *Tribolium*, but may be involved in an earlier specification of terminal fate (Schröder *et al*., 2000). Thus, it appears that an important shift occurred in *tailless* function during the transition from short-germ to long-germ embryogenesis. This situation contrasts with the conservation of *tailless* late expression in the developing forebrain of insects and vertebrates. Using mutants demonstrated an essential role for *tailless* in eye formation of *Drosophila* (Daniel *et al*., 1999; Hartmann *et al*., 2001) and the mouse (Monaghan *et al*., 1997; Yu *et al*., 2000). In conclusion, the primary conserved function for *tailless* would be in the development of the forebrain, while its role in segmentation was probably acquired during the evolution of long-germ holometabolous insects. Other gap genes such as *orthodenticle*, *empty spiracles*, or *hunchback* are known to be part of a conserved neural network that was recruited for insect segmentation (Reichert, 2002).

3.6.3.1.2.5. PNR One NR2E3 gene, homologous to the vertebrate photoreceptor-specific nuclear receptor (PNR; Kobayashi *et al.*, 1999), was identified in the genome of *Drosophila* (Flybase: CG16801) and *Anopheles* (Bertrand *et al.*, in press). Nothing is known about this gene in insects. It is of note that PNR expression is restricted to the retina and plays a critical role in the development of photoreceptors (Kobayashi *et al.*, 1999; Haider *et al.*, 2000). Therefore, both *tailless* and PNR play an important role during vertebrate eye development. We have seen that the role of *tailless* in the formation of the visual system is conserved between insects and vertebrates. Whether the same conservation exists for PNR remains to be established.

3.6.3.1.2.6. DSF The NR2E4 nuclear receptor (*dissatisfaction*, DSF) may be specific to insects. It has been identified in *D. melanogaster* (Finley *et al.*, 1998), *D. virilis* (Pitman *et al.*, 2002), *Anopheles* (Bertrand *et al.*, in press), and *Manduca* (Pitman *et al.*, 2002), but no homologs are found in nematodes and chordates. Recent analysis of genomic data suggest that DSF is one of the four nuclear receptors (along with HR39, E78, and FAX1) that were lost in the chordate lineage (Bertrand *et al.*, in press). DSF is necessary for appropriate sexual behavior and sex-specific neural development. It acts downstream of the genes *Sex lethal* and *transformer* in the sex determination cascade. Mutant females resist male courtship and fail to lay eggs, while mutant males are bisexual and mate poorly (Finley *et al.*, 1997; O'Kane and Asztalos, 1999). The *dsf* gene is expressed in a very limited set of neurons in the brain of larvae, pupae, and adults, with no sex specificity (Finley *et al.*, 1998). The DSF protein acts as a repressor, through its LBD and an unusually very long hinge region (Pitman *et al.*, 2002). It will be very interesting to test whether DSF can also act as a ligand-dependent activator, since no sex hormones are known in insects (De Loof and Huybrechts, 1998).

3.6.3.1.2.7. FAX1 The NR2E5 gene, called FAX-1, was first identified in *Caenorhabditis* as a regulator of axon pathfinding and neurotransmitter expression (Wightman *et al.*, 1997). FAX-1 is expressed in embryonic neurons after neurogenesis but just prior to axon extension (Much *et al.*, 2000). Homologs were identified in the genome of *Drosophila* (Flybase: CG10296) and *Anopheles* (Bertrand *et al.*, in press). The *fax-1* genes probably experienced a rapid evolution in Ecdysozoa, since they are very divergent from all the other genes of the NR2E group of nuclear receptors.

3.6.3.1.3. Subfamily 3: ERR a classical steroid receptor in insects? The subfamily NR3 comprises the receptors for sex and adrenal steroid hormones: estrogens (ER), androgens (AR), progesterone (PR), glucocorticoids (GR), and mineralocorticoids (MR), as well as ERR which is an orphan receptor related to ER. Until recently, these proteins were believed to be restricted to vertebrates. However, not only is one ERR gene present in the urochordate *Ciona intestinalis* (Yagi *et al.*, 2003) and in Diptera, but an ER ortholog was isolated from a mollusk (Thornton *et al.*, 2003). Therefore, it appears that, to the exclusion of ERR, steroid receptors from the subfamily NR3 were specifically lost in ecdysozoans (Bertrand *et al.*, in press). Unfortunately, the precise relationships between ER, ERR, and the other steroid receptors are difficult to determine with the current data.

One ERR gene (NR3B4) is present in the genome of *Drosophila* (Adams *et al.*, 2000; Östberg *et al.*, 2003) and *Anopheles* (Bertrand *et al.*, in press). It was also found independently in a screen for *Drosophila* embryonic neural precursor genes (Brody *et al.*, 2002). There is no ortholog of ERR in the *Caenorhabditis* genome (Maglisch *et al.*, 2001). In vertebrates, the three ERR genes have broad expression patterns and influence a wide range of physiological processes, including those governed by ERs (Giguere, 2002). A striking contrast between vertebrate and insect endocrinology is the lack of sex determining hormones in insects (De Loof and Huybrechts, 1998). Obtaining functional data for *Drosophila* and/or *Anopheles* ERR could help to tackle this intriguing problem.

3.6.3.1.4. Subfamily 4: HR38, an alternative partner for USP-RXR The subfamily NR4 is a small group of orphan nuclear receptors: the vertebrate's NGFIB α βγ, divergent nematode receptors (NHR-6 in *C. elegans*) and the insect HR38 (Sluder and Maina, 2001; Laudet and Gronemeyer, 2002). The HR38 gene (NR4A4) has been cloned in *Drosophila* (Fisk and Thummel, 1995; Sutherland *et al.*, 1995; Komonyi *et al.*, 1998), *Aedes* (Zhu *et al.*, 2000), and *Bombyx* (Sutherland *et al.*, 1995).

Remarkably, like their vertebrate homologs NGFIB, insect HR38 can bind DNA either as a monomer or through an interaction with USP-RXR (Sutherland *et al.*, 1995; Crispi *et al.*, 1998; Zhu *et al.*, 2000). This interaction plays a very interesting role in the mosquito *Aedes*. In this insect, vitellogenesis requires a blood meal that triggers a 20E cascade to activate yolk synthesis (see **Chapter 3.9**). Before a blood meal, this regulation is inhibited despite the presence of the hormone.

A key factor of this inhibition is the competitive binding of HR38 to USP-RXR, which prevents the formation of the ECR/USP-RXR heterodimer, the functional EcR (Zhu *et al.*, 2000; Raikhel *et al.*, 2002). Therefore, although HR38 is not directly regulated by 20E, it can participate in the 20E pathway as an alternative partner to USP-RXR. In *Drosophila*, HR38 is expressed in ovaries and during all stages of development. Different mutant alleles have different lethal phases, from larval stages to adults, showing a role in metamorphosis and adult epidermis formation (Kozlova *et al.*, 1998). Recent results have shown that the *Drosophila* heterodimer HR38/USP-RXR responds to a distinct class of ecdysteroids independently of ECR and without direct binding of the ligand to either HR38 or USP-RXR. In fact, crystal structure analysis reveals that the *Drosophila* HR38 LBD lacks both a conventional ligand binding pocket and a bona fide AF2 transactivation domain (Baker *et al.*, 2003). Interestingly, the vertebrate NGFIB receptors are ligand independent transcriptional activators that are considered to be real orphans, a view which was recently reinforced by structural analysis (Wang *et al.*, 2003). These data provide strong evidence that NR4 receptors operate through an atypical mechanism of activation.

3.6.3.1.5. Subfamily 5: competition in the ecdysone pathway The subfamily NR5 contains orphan nuclear receptors that, together with NR2, are believed to be at the origin of the superfamily (Escriva *et al.*, in press). In mammals, the subfamily NR5 contains three homologs, including the steroidogenic factor 1 (SF1), an essential regulator of endocrine function (Parker *et al.*, 2002). One ortholog (*nhr-25*) is present in the genome of *Caenorhabditis* (Gissendanner and Sluder, 2000). In insects, the two NR5 genes, FTZ-F1 and HR39, are important in the ecdysone (20E) pathway.

3.6.3.1.5.1. FTZ-F1 The FTZ-F1 gene (NR5A3) is one of the best-known nuclear receptors of insects. This gene encodes two protein isoforms, α and β, each having a specific role. The αFTZ-F1 isoform acts during segmentation of the early embryo, a function that is likely to be an innovation of holometabolous insects. The βFTZ-F1 isoform is a major regulator of metamorphosis, a role probably shared by all ecdysozoans. Interestingly, FTZ-F1 has been cloned not only in Diptera (Lavorgna *et al.*, 1991, 1993; Li *et al.*, 2000) and Lepidoptera (Sun *et al.*, 1994; Weller *et al.*, 2001), but also in the honeybee, *Apis mellifera* (Hepperle and Hartfelder, 2001), *Tenebrio* (Mouillet *et al.*, 1999), and in the shrimp *Metapeneus ensis* (Chan and Chan, 1999). Only ECR and USP-RXR have been identified in such a wide sample of arthropod species (**Figure 6**).

The *Drosophila* αFTZ-F1 is a direct regulator of the pair-rule gene *fushi-tarazu* (*ftz*), which governs the formation of embryonic metameres (Ueda and Hirose, 1990; Lavorgna *et al.*, 1991; Ohno *et al.*, 1994). Later, it was also found that αFTZ-F1 and FTZ are mutually dependent cofactors for regulation of target genes such as *engrailed*, *wingless*, or *ftz* itself (Florence *et al.*, 1997; Guichet *et al.*, 1997; Yu *et al.*, 1997). This interaction requires the DBD of both proteins as well as a contact between a LRALL domain of the FTZ protein with the AF-2 activation domain of αFTZ-F1 (Schwartz *et al.*, 2001; Suzuki *et al.*, 2001; Yussa *et al.*, 2001). The LRALL domain matches the consensus box LxxLL that is found in many cofactors of nuclear receptors (Laudet and Gronemeyer, 2002). Such a partnership between a homeodomain protein and a nuclear receptor is still a unique example in insects (Yussa *et al.*, 2001). It raises the exciting possibility that nuclear receptors may interact with *Hox* genes. Indeed, *ftz* is a member of the arthropod *Hox* gene family. However, it is a very derived *Hox* gene, which has lost its homeotic function in insects and acquired new roles in neurogenesis and segmentation (Hughes and Kaufman, 2002). Thus, it was interesting to determine whether the LxxLL box was conserved in the FTZ proteins. Elegant experiments, both *in vitro* and *in vivo*, revealed a progressive evolution of FTZ in insects. The pair-rule function is moderately conserved in *T. castaneum* and absent in the *Schistocerca*. Furthermore, this functional evolution correlates with the presence of a LxxLL domain in the FTZ protein of the holometabolous insects *Drosophila* and *Tribolium*, and its absence in the hemimetabolous grasshopper *Schistocerca* (Alonso *et al.*, 2001; Lohr *et al.*, 2001). In conclusion, it appears that the *ftz* gene gained one of the domains that facilitate the interaction between αFTZ-F1 and FTZ somewhere in the emergence of holometabolous insects.

The isoform βFTZ-F1 plays a central role during molting and metamorphosis of *Drosophila*. It is repressed by 20E and its expression, which occurs during mid-prepupa when the titer of 20E is low, activates the late prepupal genes (Lavorgna *et al.*, 1993; Woodard *et al.*, 1994). Its activation requires HR3 (Kageyama *et al.*, 1997; White *et al.*, 1997), an interaction that is also used during vitellogenesis of *Aedes* (Li *et al.*, 2000) (see **Chapter 3.9**). Analysis of mutants shows that βFTZ-F1 provides competence for stage-specific responses to 20E throughout the organism (Broadus *et al.*, 1999; Yamada

et al., 2000). These general characteristics seem to be well conserved in Lepidoptera, as shown by expression and induction experiments made with *Bombyx* (Sun *et al.*, 1994) and *Manduca* (Hiruma and Ridifford, 2001; Weller *et al.*, 2001). In fact, the patterns of expression observed in *Tenebrio* (Mouillet *et al.*, 1999) and the shrimp *M. ensis* (Chan and Chan, 1999), together with the mutant analysis of the *Caenorhabditis* homologous gene *nhr-25* (Asahina *et al.*, 2000; Gissendanner and Sluder, 2000) suggest that the role of βFTZ-F1 may be very similar in all Ecdysozoa. A promising result is that βFTZ-F1 could be one of the factors controlling honeybee caste development (see **Chapter 3.13**). In this social insect, JH and ecdysteroids induce a dramatic reduction in ovariole number during the fourth larval instar of workers but not in queens. In a search for genes controlling this phenotypic plasticity, the βFTZ-F1 of *A. mellifera* was identified by differential display of RT-PCR as a 20E down-regulated gene in the larval ovary (Hepperle and Hartfelder, 2001). This pioneering work highlights one of the most interesting putative functions for nuclear receptors: molecular regulation of polyphenism (Nijhout, 2003) (see **Chapter 3.13**).

3.6.3.1.5.2. HR39 The HR39 gene (NR5B1) exists in *Drosophila* (Ohno and Petkovich, 1992; Ayer *et al.*, 1993), *Anopheles* (Bertrand *et al.*, in press), and *Bombyx* (Niimi *et al.*, 1997) but not in vertebrates. Note that this gene was initially described with the misleading name of FTZ-F1β but should not be confused with the β isoform of FTZ-F1 (NR5A3). This second group of subfamily NR5 was previously seen as the result of a duplication that arose during insect evolution (Laudet and Gronemeyer, 2002). However, the identification of an HR39 homolog in *Schistosoma mansoni*, a platyhelminth parasite of humans, suggests that the FTZ-F1/HR39 duplication occurred very early during protostomian evolution (de Mendonça *et al.*, 2002). The *Caenorhabditis* genome has one FTZ-F1 gene (*nhr-25*) but no HR39 homolog (Sluder and Maina, 2001). The HR39 gene of *Drosophila* is induced by 20E and expressed at every stage of development, with a maximum at the end of third larval and prepupal stages (Horner *et al.*, 1995). Therefore, contrary to βFTZ-F1, it behaves like an early gene during the onset of metamorphosis. Remarkably, the pattern of expression of *Schistosoma* HR39 resembles that of *Drosophila*, with the highest amounts in the larval form (de Mendonça *et al.*, 2002). Both HR39 and FTZ-F1 bind as monomers to the same response elements (Ayer and Benyajati, 1992, 1993; Ohno and Petkovich, 1992; Crispi *et al.*, 1998). Overexpression of HR39 or FTZ-F1 have opposite effects on promoter activity, suggesting competition between these two nuclear receptors (Ayer *et al.*, 1993; Ohno *et al.*, 1994).

3.6.3.1.6. Subfamily 6: HR4, a new early–late gene? The HR4 gene (NR6A2) is homologous to germ cell nuclear factor (GCNF), an orphan nuclear receptor of vertebrates. It has been identified in the genome of *Drosophila* (Adams *et al.*, 2000) and *Anopheles* (Bertrand *et al.*, in press), in the lepidopterans *Manduca* (Weller *et al.*, 2001), *Bombyx* (Charles *et al.*, 1999), and *Trichoplusia ni* (Chen *et al.*, 2002) as well as in *Tenebrio* (Mouillet *et al.*, 1999). One homolog is also found in nematodes (Sluder and Maina, 2001), showing that there might be one single NR6A gene in all metazoans. For once, *Drosophila* is not the leading model organism in the study of an insect nuclear receptor, since most of our current information on HR4 come from *Tenebrio* and lepidopteran species. Several lines of evidence suggest that HR4 may be a new early–late gene involved in the onset of metamorphosis. First, HR4 is directly inducible by 20E in *Manduca* (Hiruma and Riddiford, 2001) and in a *Trichoplusia* cell line (Chen *et al.*, 2002). Then, its activation during molting and metamorphosis starts after the early gene HR3 and before the mid-prepupal gene FTZ-F1. *Manduca*, *Bombyx*, and *Tenebrio* share this pattern of expression (Charles *et al.*, 1999; Mouillet *et al.*, 1999; Hiruma and Riddiford, 2001; Weller *et al.*, 2001). Finally, preliminary results obtained with *Drosophila* confirm that HR4 plays an essential role during molting and metamorphosis (King-Jones and Thummel, FlyBase). However, as for many other nuclear receptors, the most conserved functions are probably in embryogenesis and gametogenesis. Indeed, in adult vertebrates, GCNF is predominantly expressed in the germ cells of gonads, and loss of GCNF function causes embryonic lethality (Chung and Cooney, 2001). Furthermore, the *Drosophila* HR4 gene was also identified in an enhancer-trap screen for novel X-linked essential genes. The P-insertion (PL78) located in this gene causes embryonic lethality with observable cuticular defects and reveals that *Drosophila* HR4 is expressed in embryonic gut and ovary (Bourbon *et al.*, 2002).

3.6.3.1.7. Subfamily 0: atypical transcription factors KNI, KNRL, and EG The subfamily 0 was artificially created to encompass all the proteins that contain only one of the two conserved domains (DBD: NR0A or LBD: NR0B) of the nuclear receptors (nuclear receptors nomenclature committee, 1999). In insects, three transcription factors have

been classified in the subfamily NR0A because they lack a LBD but contain a DBD similar to the one found in the superfamily (Laudet, 1997). This group contains three genes that have been cloned only in Diptera: *knirps* (KNI, NR0A1), *knirps-related* (KNRL, NR0A2), and *eagle* (EG, NR0A3). No homolog can be found in nematodes and vertebrates, suggesting that this group may be specific to insects or arthropods. On phylogeny based with the DBD, these genes are distantly related to HR96 and ECR, typical nuclear receptors of subfamily NR1 (Laudet, 1997).

The gap gene *knirps* has been identified in *D. melanogaster* (Nauber *et al*., 1988), *D. virilis* (Gerwin *et al*., 1994), *D. americana*, *D. novamexicana* (Wittkopp *et al*., 2003), and *Musca* (Sommer and Tautz, 1991) but, surprisingly, it is absent from the genome of *Anopheles* (Bertrand *et al*., in press). KNRL and EG are present both in *Drosophila* and *Anopheles* (Oro *et al*., 1988; Rothe *et al*., 1989; Higashijima *et al*., 1996; Bertrand *et al*., in press). The chromosomal location of these genes, at the proximal part of the left arm of the third chromosome, is conserved between *Drosophila* and *Anopheles*. These data suggest that *knirps* may be the result of a duplication of an ancestral *knrl* gene, which occurred during the evolution of brachyceran Diptera. This hypothesis is reinforced by the strong conservation of expression and function between *Drosophila knirps* and *knrl*. Indeed, both genes are functionally redundant for their role in determining the anterior head structures at the blastoderm stage (Gonzalez-Gaitan *et al*., 1994). Furthermore, they control together the development of several other organs, such as trachea (Chen *et al*., 1998), wing veins (Lunde *et al*., 1998, 2003), foregut, and hindgut (Fuss *et al*., 2001). Thus, it appears that *knirps* and *knrl*, which are very close together on the third chromosome, have conserved the same regulatory regions after duplication. An interesting difference, however, is the size of their intron sequences: one kb in *knirps* and 19 kb in *knrl*. The consequence of this difference in intron size is that *knrl* can complement *knirps* mutations only as an artificial intronless transgene. This effect is explained by the required coordination of mitotic cycle length and gene size during the rapid developmental period of gap gene expression (Rothe *et al*., 1992).

The *eagle* gene (initially named *egon*, for embryonic gonads) is required for the specification of serotonergic neurons and other neuroblasts in the embryonic and larval central nervous system of *Drosophila* (Higashijima *et al*., 1996; Dittrich *et al*., 1997; Lundell and Hirsch, 1998). This gene is present in the genome of *Anopheles* (Bertrand *et al*., in press), but nothing is known about *eagle* in other species of insects.

3.6.3.2. Conservations and Innovations

What general conclusions can be drawn from our present knowledge of the evolution of nuclear receptors in insects? First, it is likely that all insects have at least 17 different nuclear receptors, but DSF, KNI, KNRL, and EG are not included in this number, since their origin by domain recombination is poorly understood. They might well be insect-specific duplications, but this hypothesis has yet to be tested. There are 21 nuclear receptor genes in the genomes of both the brachyceran dipteran *Drosophila* (Adams *et al*., 2000) and the nematoceran dipteran *Anopheles* (Bertrand *et al*., in press). In other insects, given the absence of complete genomic sequences, the full number of these genes is not yet known. However, thanks to a wide interest in the genetics of metamorphosis, several nuclear receptors have been cloned by classical means outside Diptera. In Lepidoptera, 12 nuclear receptors have been identified (11 in *B. mori*), eight in Coleoptera (seven in *Tenebrio molitor*) seven in Hymenoptera and only three in Orthoptera (**Figure 7**). Different ongoing genome and EST sequencing projects should help to clarify this fundamental point (GOLD). Indeed, among the model organisms chosen for these projects are representatives of Hymenoptera (the honeybee *A. mellifera*), Coleoptera (the corn rootworm *D. virgifera*), crustaceans (the water flea *Daphnia*, the crab *C. pugilator*, and the shrimp *F. chinensis*), and Chelicerates (the tick *Amblyomma americanum*). Despite the current lack of heterometabolous and ametabolous insects in these projects, the sequence data will be essential to draw a comprehensive phylogenetic analysis of arthropod nuclear receptors.

With respect to functional evolution, three major trends can be seen (**Figure 8**). First, a strong conservation of structure and regulation characterize HNF4, SVP, and TLL. These proteins are the most conserved nuclear receptors in metazoans and although they may have acquired new functions in insects, their fundamental roles in patterning the embryo are likely to be very similar in all species. There is little doubt that HNF4, SVP, and TLL genes will be found in all insects and other arthropods. Second, by contrast, KNI, KNRL, and EG show an extreme divergence, with the lack of a LBD. In that respect, they cannot be considered as bona fide nuclear receptors. Third, it appears that most of the other nuclear receptors have a broad pattern of expression and participate, directly or indirectly, in

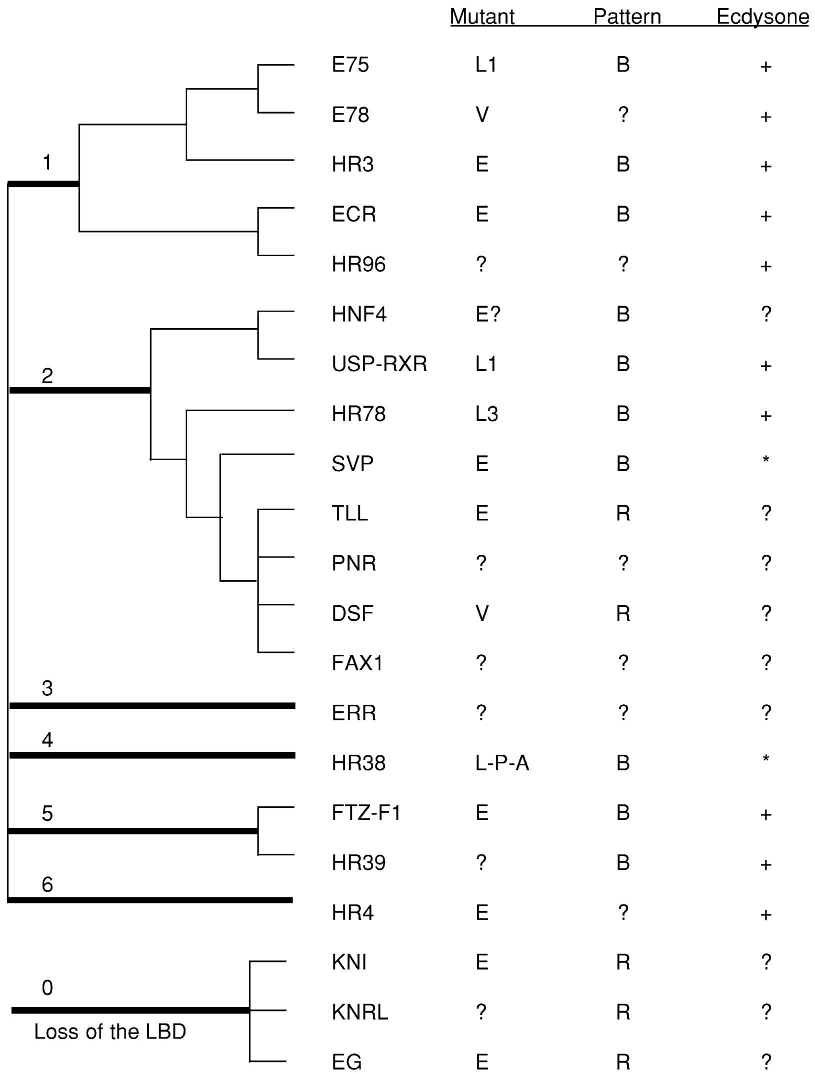

Figure 8 Developmental characteristics of insect nuclear receptors. The tree is the same as in **Figure 6**. The column on the left (mutant) indicates the stage of lethality of the *D. melanogaster* mutants: E, embryo; L, larva; L1, first instar larva; L3, third instar larva; P, pupa; A, adult. In addition, the viable phenotypes (V) are also indicated. The central column (pattern) summarizes the spatial and temporal patterns of expression in insects as broad (B) or restricted (R). The column on the right (ecdysone) indicates whether one given nuclear receptor is part of the ecdysone pathway (+) or simply interacts with it (*).

the 20E pathway (**Figure 8**) (Sullivan and Thummel, 2003). It is a general characteristic of nuclear receptors to be expressed at various stages in many different organs, therefore participating in several physiological processes. The organism uses them as powerful gene regulators whose activity can be coordinated in time and space through the availability of the appropriate ligand. The current view may be biased by the fact that the single hormone mostly related to the insect's nuclear receptor is 20E. However, this signal has undoubtedly acquired a central role in the developmental timing controlled by nuclear receptors.

3.6.4. Evolution of the Ecdysone (20E) Receptor

3.6.4.1. The Arthropod Ecdysone Receptor is a Heterodimer between ECR and USP-RXR

Within the superfamily of nuclear receptors, ECR (NR1H1) belongs to the same group as the vertebrate liver X receptors (LXRα and LXRβ__NR1H3, and NR1H2_), which are receptors for oxysterols (Laudet and Gronemeyer, 2002). USP-RXR (NR2B4) is the ortholog of vertebrate retinoid X receptors (RXRα, β, .γ NR2B1, 2, 3) (Laudet and Gronemeyer, 2002). The name USP (*ultraspiracle*)

comes from the phenotype of *Drosophila* mutants (Perrimon *et al.*, 1985), whereas RXR refers to the mammalian ligand (9-*cis* retinoic acid) (Mangelsdorf *et al.*, 1990). Both genes have not only been isolated in a large number of dipteran and lepidopteran species, but also in several other insect species and arthropods (**Figure 6**).

The functional *Drosophila* ecdysone (20E) receptor is a heterodimer of the products of the ecdysone receptor (*EcR*) and ultraspiracle (*usp*) genes (Koelle *et al.*, 1991; Oro *et al.*, 1992; Yao *et al.*, 1993). The requirement of heterodimerization between ECR and USP-RXR has been found in all the other species studied, including several dipterans (Wang *et al.*, 1998; Vögtli *et al.*, 1999), lepidopterans (Swevers *et al.*, 1996; Perera *et al.*, 1998; Lan *et al.*, 1999; Minakuchi *et al.*, 2003), the crab *C. pugilator* (Durica *et al.*, 2002), and even the tick *Am. americanum* (Guo *et al.*, 1997, 1998). Therefore, it appears that the heterodimer ECR/USP-RXR is the functional ecdysone (20E) receptor in all arthropods. It must be noted that these tests of heterodimerization were made using artificial or real *Drosophila* EcREs, and that the natural binding sites are unknown in other species. However, in *Aedes* (Wang *et al.*, 1998), as well as in *Drosophila* (Vögtli *et al.*, 1998), the heterodimer ECR/USP-RXR exhibits a broad DNA binding specificity, which is likely to be conserved among arthropods.

3.6.4.2. Divergence of the Ecdysone Receptor in Diptera and Lepidoptera

Understanding the evolution of ecdysteroid regulation in insects requires comparative analysis of both partners of the heterodimer. It has been shown that ECR and USP-RXR experienced a strong acceleration of evolutionary rate in Diptera and Lepidoptera compared with other insects (Bonneton *et al.*, 2003). In the LBD of USP-RXR there is only 49% identity between Diptera–Lepidoptera and other insects, as opposed to 68% between these other insects and other arthropods, and 70% between the other insects and chordates (**Table 1**). Thus, the USP-RXR LBD of many insects is less similar to Diptera and Lepidoptera than it is to the chordate RXRs. A similar situation holds for the DBD and LBD domains of ECR, although the divergence is less pronounced. Thus, both ECR and USP-RXR LBD sequences of Diptera and Lepidoptera have evolved at significantly different rates than other species (**Table 1**). This acceleration defines a clear separation within holometabolous insects. Diptera and Lepidoptera belong to the clade Panorpida (Kristensen, 1981), with Hymenoptera as a sister group. Panorpida also includes: Trichoptera (caddisflies), the sister group of Lepidoptera, as well as Mecoptera (scorpionflies), and Siphonaptera (fleas) which are more closely related to Diptera (**Figure 6**). A unique event of acceleration could be responsible for the accelerated evolutionary rates at the base of and within these groups.

3.6.4.3. Evolution of USP-RXR

Several protein domains for which sequence divergence is specific to Diptera and Lepidoptera have been identified (**Figure 9**). The most impressive differences affects the LBD of USP-RXR. In addition, ECR sequences show variability in other domains, namely the DNA binding and the C-terminal F domains (Bonneton *et al.*, 2003). In the *Drosophila* and *Heliothis* USP-RXR structures, the loop between helices H1 and H3 is located inside the hydrophobic furrow of the LBD, thereby preventing the repositioning of helix H12 and interactions with coactivators, and locking these USP-RXRs in an unusual antagonist conformation (Billas *et al.*, 2001; Clayton *et al.*, 2001). In the light of these results, our observation of Diptera- and Lepidoptera-specific sequence diversity in both the loop H1–H3 and the helix H12 suggests a form of concerted evolution between these two interacting regions of the USP-RXR LBD. This evolution may have changed the ligand-dependent transactivation activity of

Table 1 Identity and evolutionary rates for USP-RXR and ECR LBD

		USP-RXR LBD		*ECR LBD*	
Groups of species		*Identity (%)*	*Evolutionary rate*	*Identity (%)*	*Evolutionary rate*
Diptera-Lepidoptera/	Other insects	49	0.31***	64	0.12*
Diptera-Lepidoptera/	Other arthropods	44	0.36***	58	0.13*
Other insects/	Other arthropods	68	0.06 NS	68	0.006 NS

Values indicated for comparisons of evolutionary rates are substitution rate difference. The probability associated to the test is indicated as follows: not significant (NS) $>5\%$; * $\leq 5\%$; *** $\leq 0.5\%$. (Adapted from Bonneton, F., Zelus, D., Iwema, T., Robinson-Rechavi, M., Laudet, V., **2003**. Rapid divergence of the ecdysone receptor in Diptera and Lepidoptera suggests coevolution between ECR and USP-RXR. *Mol. Biol. Evol. 20*, 541–553.)

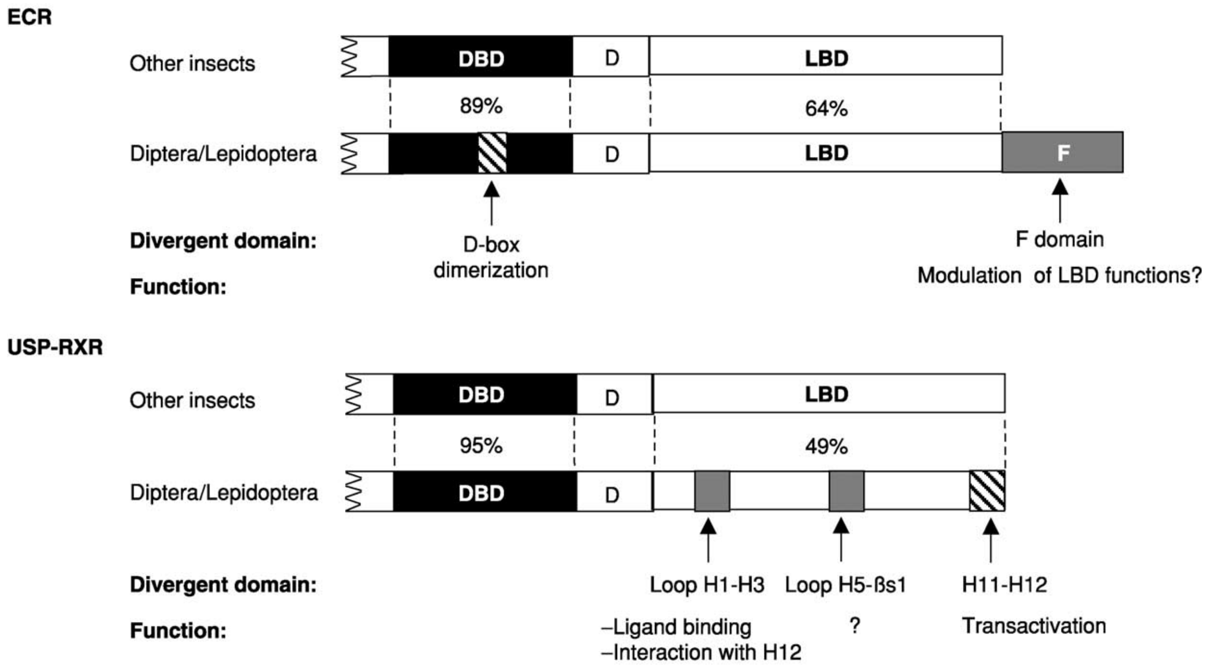

Figure 9 Protein divergence and functional domains of ECR and USP-RXR in insects. On this diagram (not to scale), the DBDs are shown in black, the LBDs in white, and the Diptera-Lepidoptera specific insertions are in grey. Dashed lines indicate regions with a strong Diptera/Lepidoptera divergence. The N-terminal A/B domain (not shown) and the linker region (D domain) are highly divergent in size and sequences and, thus, are not compared in this figure. The average identity percentages of pairwise comparisons for DBD and LBD of USP-RXR and ECR are from Bonneton *et al.* (2003). The name of each divergent domain is indicated, with its known or putative function written below.

the protein. It may also have had an effect on the ligand binding activity, since the loop H1–H3 contains residues that interact with the phospholipid cocrystallized with *Drosophila* and *Heliothis* LBD. However, given the very strong conservation of Helix H10, it is likely that the dimerization activity of USP-RXR LBD remained largely unchanged during evolution. This is important, since USP-RXR is the heterodimeric partner of numerous nuclear receptors, both in vertebrates (TR, RAR, PPAR, LXR, FXR, CAR, NGFIB, etc.) and in insects (HR38, SVP, HR78).

All these hypotheses can now be tested both *in vitro* and, more importantly, *in vivo* using transgenesis. Small changes at the molecular level can lead to important functional differences that may be revealed only by studying their consequences in whole organisms. For example, replacing the domains D and E of the *Drosophila usp* gene with the equivalent domains of another dipteran, *Chironomus*, allows the rescue of usp mutants from first instar larvae lethality, but do not restore a normal metamorphosis (Henrich *et al.*, 2000). Therefore, despite the 72% of similarity between the exchanged domains, this chimeric USP-RXR fails to function normally in *Drosophila*. Similar studies involving smaller chimeric regions and site directed mutations should help in the future to identify which domains contributed to the functional evolution of USP-RXR in insects.

3.6.4.4. Evolution of ECR

It is intriguing that the LBD of ECR underwent a significant increase of substitution rate in Diptera and Lepidoptera, while its structure remained apparently largely unchanged. In all insects, and presumably in all arthropods, ECR LBD binds 20E (Riddiford *et al.*, 2000). This fundamental interaction may represent the primary selective constraint acting on this domain. However, the ligand affinity of ECR can show subtle differences in insects. This is best illustrated within Diptera. A homology model of the *Chironomus* ECR LBD showed that the putative ligand binding pocket is strongly conserved in all arthropods (Wurtz *et al.*, 2000). Nevertheless, comparative tests of toxicity and receptor affinity of nonsteroid insecticides revealed that the *Chironomus* ecdysone (20E) receptor behaves more like a lepidopteran than like *Drosophila* (Smagghe *et al.*, 2002). Also of great interest is the discovery that the *Aedes* receptor is significantly much more sensitive to ecdysone than the *Drosophila* receptor, whereas both proteins exhibit the same sensitivity to 20E, the natural biologically active hormone. Surprisingly, the genetic origin of this difference in

ligand specificity was mapped into the helix H10 of the ECR LBD, a region known to be essential for dimerization (Wang *et al.*, 2000). These results show that the conservation of the structure of ECR LBD can hide a significant plasticity, which can only be revealed through appropriate functional tests.

Nuclear receptor LBDs are also involved in heterodimerization activity. The rapid evolution of ECR can be explained by adaptation to the extremely divergent USP-RXR, and eventually acquisition of new partners, such as HR38 (Baker *et al.*, 2003). It may be that the stability of the heterodimer required compensatory changes in ECR and USP-RXR, suggestive of coevolution. The differences seen in ECR DBD also suggest functional changes in dimerization (Bonneton *et al.*, 2003). Indeed, four of the six substitutions that are conserved among Diptera and Lepidoptera are located in the second zinc finger, at positions known to be involved in protein dimerization but not in DNA contact or nuclear localization signal (Black *et al.*, 2001; Khorasanizadeh and Rastinejad, 2001).

Another evolutionary acquisition of Diptera and Lepidoptera is the presence of a C-terminal F domain of variable length, which does not show any sequence conservation between species (**Figure 8**; Bonneton *et al.*, 2003). Most nuclear receptors do not contain this domain, including mammalian homologs LXRs. This difference is interesting, since it is known that when present (ERα, HNF-4) the F domain of nuclear receptors can modulate different functions of the LBD (Montano *et al.*, 1995; Nichols *et al.*, 1998; Peters and Khan, 1999). The F domain of *Drosophila* ECR may also contribute modestly to the activation function of the LBD (Thornmeyer *et al.*, 1999; Hu *et al.*, 2003).

3.6.4.5. Ecdysone Receptor and the Evolution of Insects

Ecdysteroids control reproduction and development of arthropods. As a result, the pattern of expression of the ecdysone (20E) receptor correlates very well in time and space with the localization and the level of these hormones. Indeed, both ECR and USP-RXR are expressed in a wide range of tissues during oogenesis, embryogenesis, molting, and metamorphosis (see **Chapter 3.5**). Therefore, any evolutionary change in the mode of action of the ecdysone receptor can have important consequences for development and/or reproduction. This major issue has only started to be addressed, and most of the questions are still unanswered.

Changing the regulation of a key developmental gene is probably one of the most effective ways to create new functions rapidly during the course of evolution. In that respect, very interesting results have shown that alterations in the timing of ovarian ECR and USP-RXR expression characterize the evolution of larval reproduction in two species of gall midges (Hodin and Riddiford, 2000). In these dipterans, pedogenesis involves the precocious growth and differentiation of the ovary and subsequent parthenogenetic reproduction in an otherwise larval form. Genetic analysis has shown that ECR and USP-RXR regulate the timing of ovarian morphogenesis during *Drosophila* metamorphosis (Hodin and Riddiford, 1998). These data suggest that heterochronic shifts in the ovarian regulation of both genes may play an important role in the evolution of dipteran pedogenesis. In a larger perspective, a growing number of evidence suggest that the genetic cascade triggered by ecdysteroids may play a central role in the control of developmental timing in Ecdysozoa (Thummel, 2001). Therefore, we can expect that future studies will identify changes in the expression of the ecdysone receptor associated with the evolution of different temporally regulated processes of insects such as, for example, molting, metamorphosis, diapause, and adult longevity.

Regarding the evolution of postembryonic development, it is observed that the divergence of EcR does not correlate with the different types of insect metamorphosis (Bonneton *et al.*, 2003). Moreover, several nuclear receptors such as E75, HR3, HR78, βFTZ-F1, and HR4 play very similar roles in the control of molting and metamorphosis amongst insects (see **Chapter 3.5**). These results suggest that the ecdysteroid-induced genetic cascade (at least the upstream part of this cascade) is a well-conserved developmental module in insects; this conclusion may even be extended to all the molting metazoans. Actually, theories that try to explain the evolution of insect metamorphosis usually consider that JH is the key player, rather than 20E (Sehnal *et al.*, 1996; Truman and Riddiford, 1999, 2002). A heterochronic shift in embryonic JH secretion, with an earlier appearance of this hormone, could well have been the major event in the transition from hemimetabolous to holometabolous insects. In the light of these interpretations, the possibility that JH is a natural ligand of USP-RXR (Jones and Sharp, 1997; Jones *et al.*, 2001; Sasorith *et al.*, unpublished data) is one of the most important point to clarify in order to understand the emergence of metamorphosis in insects.

Acknowledgments

We thank Barbara Demeinex and Hector Escriva for their very helpful comments on this text, and Gilles

Parmentier for the search of nuclear receptors in honeybee's EST. Work from our laboratory is funded by the CNRS, the MENRT, the Région Rhône-Alpes, and the ARC.

3.7 The Juvenile Hormones

W G Goodman, University of Wisconsin–Madison,
Madison, WI, USA
N A Granger, University of North Carolina,
Chapel Hill, NC, USA

3.7.1. Introduction

The juvenile hormones (JHs) represent a family of acyclic sesquiterpenoids that are, with a single known exception, unique to the class Insecta. They are the principal products of the corpora allata (CA), retrocerebral paired or unpaired endocrine glands of ectodermal origin (Wigglesworth, 1970). One or more JHs have been identified in approximately 100 insect species spanning at least 10 insect orders, from the most ancestral to the most highly derived. From an evolutionary standpoint, the JHs may have originally been involved in orchestration of reproductive processes such as control of gonadal development and vitellogenin synthesis. The role of JH in the more highly derived insect orders has expanded considerably to include regulation of metamorphosis, caste determination, behavior, diapause, and various polyphenisms (Nijhout, 1994). This chapter will present the current status of our knowledge about the JHs, their evolution, roles in embryological and larval development, biosynthesis, transport, catabolism, and molecular mode of action. The role of JH in reproduction is covered elsewhere (see **Chapter 3.9**).

3.7.2. Chemistry of the Juvenile Hormones

3.7.2.1. Discovery of the Major Juvenile Hormone Homologs

Elucidation of the chemical structures of the JHs began with Röller and colleagues, who identified the principal JH in lipid extracts of *Hyalophora cecropia* (Röller *et al.*, 1967). This first JH, methyl (2*E*,6*E* 10-*cis*)-10,11-epoxy-7-ethyl-3,11-dimethyl-2, 6-tridecadienoate, was termed JH I, and since that time, eight molecules with similar aliphatic sesquiterpene structures have been identified in insects (**Figure 1**). The structure was confirmed as the 2*E*,6*E*, 10 *cis* isomer (Dahm *et al.*, 1968), while the absolute configuration of JH I at its chiral centers (C10 and C11) was determined to be 10*R*,11*S* (Faulkner and Petersen, 1971; Nakanishi *et al.*, 1971; Meyer *et al.*, 1971).

Meyer *et al.* (1968) subsequently identified a minor component in the *H. cecropia* extracts that differed from JH I by a methyl, instead of an ethyl group at C7 (**Figure 1**). Termed JH II, methyl (2*E*, 6*E* 10-*cis*)-10,11-epoxy-3,7,11-trimethyl-2,6-tridecadienoate), like JH I, displays an *E,E* configuration at C2, C3 and C6, C7. The absolute configuration at the C10, C11 positions for the naturally occurring JH II has not been rigorously determined (Baker, 1990); however, in binding studies, (10*R*,11*S*)-JH II bound with nearly the same affinity to the *Manduca sexta* hemolymph juvenile hormone binding protein as (10*R*,11*S*)-JH I (Park *et al.*, 1993). Thus, it is likely that the naturally occurring enantiomers of JH I and II display the same 10*R*,11*S* configuration.

The third JH homolog, JH III, methyl 10,11 epoxyfarnesoate, was identified from medium in which CA of the tobacco hornworm, *M. sexta*, had been maintained (Judy *et al.*, 1973) (**Figure 1**). JH III differs from the higher homologs in that the three branches of the carbon skeleton at C3, C7, and C11 are methyl groups; however, it displays the same 2*E*,6*E* geometry. The hormone has only one chiral carbon, C10, which, in the naturally occurring hormone, displays the 10*R* configuration. JH III is the only, or predominant, JH in all insects except Lepidoptera (Schooley *et al.*, 1984). Interestingly, JH III had been chemically synthesized a decade earlier, before it was recognized as a naturally occurring hormone (Bowers *et al.*, 1965). A fourth and fifth JH (**Figure 1**), the trihomosesquiterpenoids JH 0 and its isomer, 4-methyl JH I (iso-JH 0), were identified in *M. sexta* eggs (Bergot *et al.*, 1981a), but nothing is currently known of their functions.

More recently, JH III with a second epoxide substitution at C6,C7 was isolated and identified from *in vitro* cultures of larval ring glands of *Drosophila melanogaster* (Richard *et al.*, 1989) (**Figure 1**). This homolog, termed JH III bisepoxy (JHB_3), is active in a *D. melanogaster* bioassay and has been found in other higher Diptera (Borovsky *et al.*, 1994a; Moshitzky and Applebaum, 1995; Yin *et al.*, 1995).

3.7.2.2. Hydroxylated Juvenile Hormones

Hydroxylation reactions are frequently associated with the inactivation of bioreactive molecules but in certain cases, hydroxylation can actually increase the biological potency of a compound. This important biochemical reaction appears to be involved in

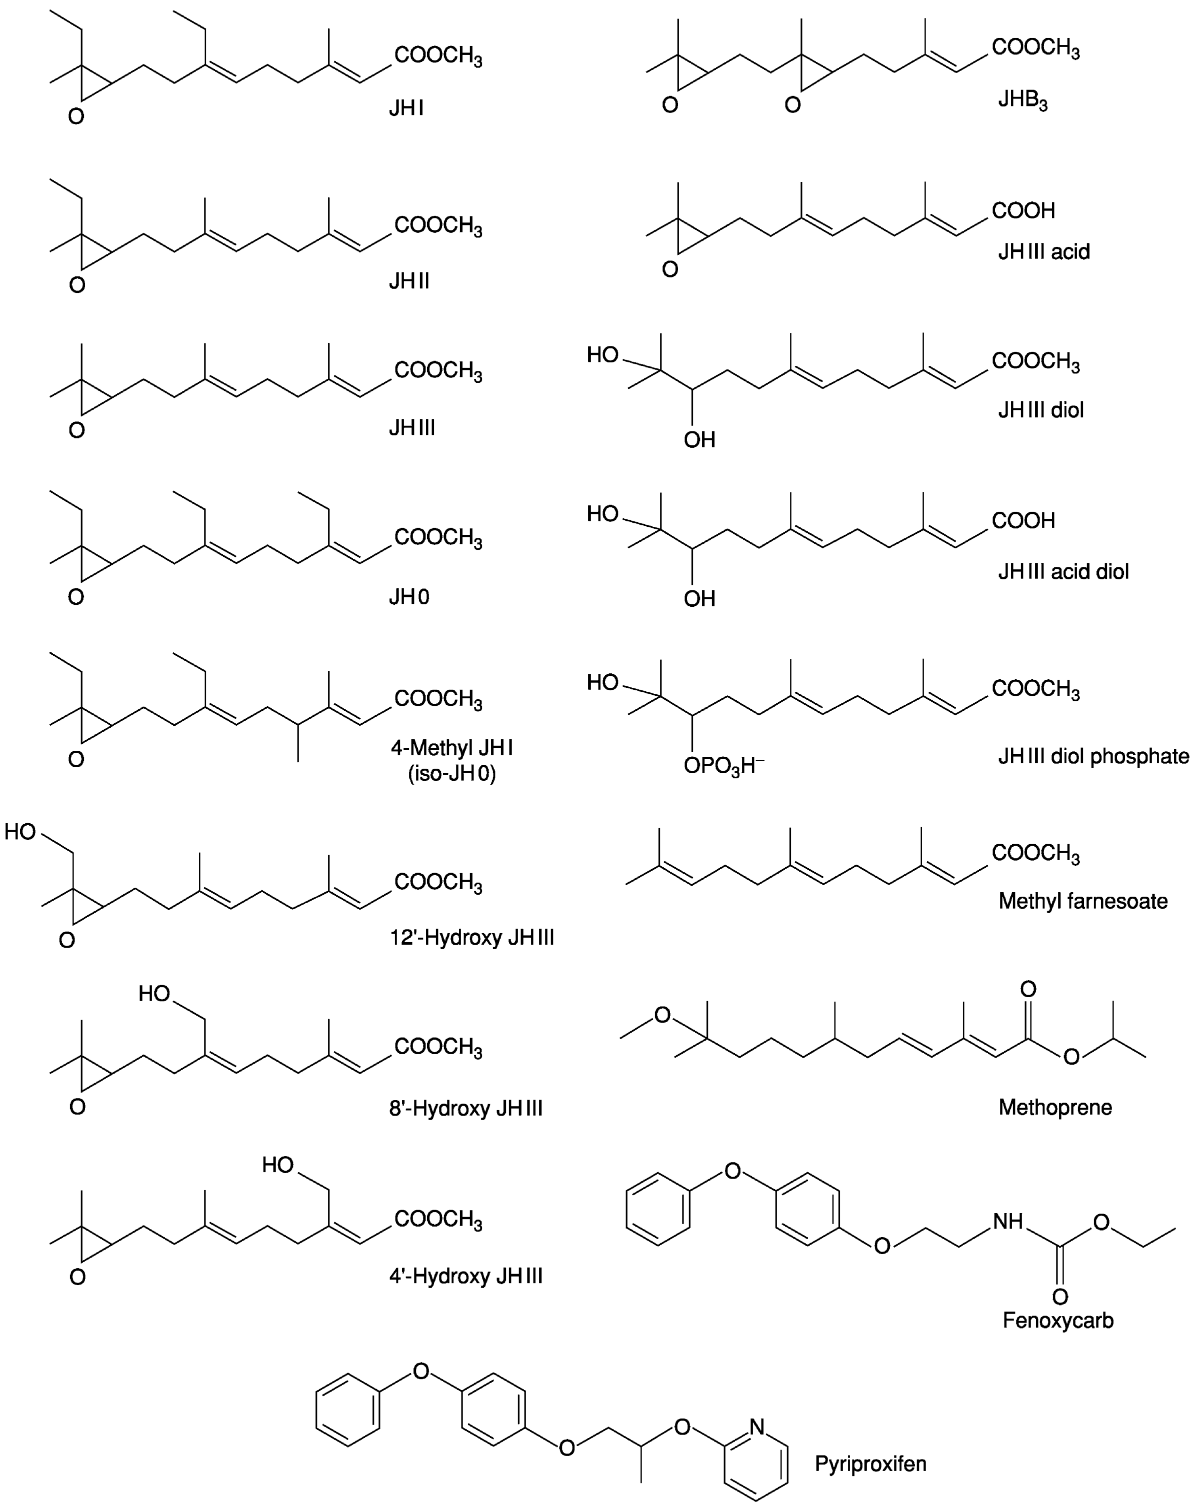

Figure 1 Chemical structures of the naturally occurring juvenile hormone (JH) homologs, hydroxylated JHs, JH metabolites, and commonly used JH analogs.

the production of a new group of JH homologs, the hydroxylated JHs (HJHs). These HJHs, 4-OH, 8-OH, and 12-OH JH III, are synthesized and released by the CA of the African locust, *Locusta migratoria* (Darrouzet *et al*., 1997, 1998; Mauchamp *et al*., 1999) (**Figure 1**). The biological activity of synthetic 12-OH JH III was bioassayed utilizing *Tenebrio molitor* and was found to be 100-fold more active than JH III (Darrouzet *et al*., 1997). This result may reflect the cross-species nature of the bioassay,

since the assay using *L. migratoria* is not sufficiently sensitive (see Section 3.7.5.1).

While the biosynthetic pathway for the synthesis of the HJHs has not been determined, two pathways have been suggested: (1) hydroxylation of the JH III structure itself or (2) incorporation of hydroxylated precursors into the JH backbone via the isoprenoid biosynthetic pathway (Darrouzet *et al.*, 1998). A cytochrome P450, *CYP4C7*, identified in the cockroach *Diploptera punctata*, can catalyze the formation of 12-OH JH III and (10*E*)-12-OH farnesol, indicating that hydroxylation of JH III appears to be a primary reaction in the CA (Sutherland *et al.*, 1998). However, there is a sharp increase in the expression of this enzyme when JH is absent or when there is an intrinsic repression of JH synthesis, suggesting that hydroxylation of JH is a mechanism for inactivating the hormones. The pathways of synthesis and the physiological roles of the HJHs remain a fertile area for investigation.

3.7.3. Other Naturally Occurring Juvenile Hormones

Davey (2000a), in a thought-provoking essay, posed an intriguing question: "How many JHs are there?" Using a chemical definition, i.e., that JH is a farnesoid molecule secreted by the CA, one can count but a handful. However, if a JH is defined by its biological activity, the JHs could include HJHs, catabolic products, and nontraditional molecules, increasing the number significantly and creating the difficult problem of sorting out which molecules are actually JHs.

3.7.3.1. Metabolites of Juvenile Hormones as Hormones?

An open mind is needed when considering whether metabolites of JH could serve as substrate for conversion to the biologically active hormone or perhaps could act as hormones themselves. A group of molecules that has long been overlooked and frequently relegated to a mere biochemical curiosity are the JH conjugates (Roe and Venkatesh, 1990). Polar metabolites of JH I that are cleaved by glucosidases and sulfatases were identified in flies nearly three decades ago (Yu and Terriere, 1978), and more recent studies hint at the existence of very polar metabolites of JH. A major metabolite resulting from the injection or application of JH II into wandering larvae and prepupae of the cabbage looper, *Trichoplusia ni*, was found to be an unidentified, water-soluble polar product of the hormone (Kallapur *et al.*, 1996). Identification by radio high-performance liquid chromatography (HPLC), as well as mass spectrometry, has confirmed that the molecule is a novel polar metabolite and that it is not a JH diol phosphate (M. Roe, personal communication). *In vitro* studies on the biosynthetic products of the CA from *M. sexta* and two other lepidopteran species indicate that the glands are synthesizing JH conjugates not recognized by antibodies highly specific for the JHs and their acids; nevertheless, when these compounds are hydrolyzed by esterases, JH III acid is formed (Granger *et al.*, 1995a). This product also appears to exist in the hemolymph, and the results of this study suggest the moiety is either a glucuronide of JH III or an acylglycerol with JH III as the side chain(s).

Schooley's group identified other polar metabolites in the hemolymph of *M. sexta* as phosphate conjugates of JH I and JH III diol and found that JH I diol phosphate (**Figure 1**) is the principal end product of JH I metabolism in *M. sexta* (Halarnkar and Schooley, 1990; Halarnkar *et al.*, 1993). More recently, Maxwell *et al.* (2002a, 2002b) identified the enzyme responsible for catalyzing the conversion of the JH diol to the JH diol phosphate, JH diol kinase (JHDK), and proposed that cellular JH epoxide hydrolase (JHEH) and JHDK are primarily responsible for the irreversible inactivation of JH early in the last stadium of *M. sexta*, when the JH titer rapidly decreases (Baker *et al.*, 1987) (see Section 3.7.9).

At the present time, there appear to be only two definitive pathways for the catabolism of JH: (1) hydrolysis of the methyl ester of JH by hemolymph esterases, yielding JH acid, and (2) hydration of the epoxide by JHEH, yielding JH diol (Roe and Venkatesh, 1990) (**Figures 1** and **2**). Can any of these catabolites act as a JH? There is certainly evidence that JH acid can be converted to JH and that it may also act as a hormone. It has been known for a number of years that JH acids are secreted by the CA of *M. sexta* beginning early in the last larval stadium (Janzen *et al.*, 1991) and that they are apparently the sole product of the CA by the wandering stage in this stadium (Sparagana *et al.*, 1984; Janzen *et al.*, 1991) (**Figure 3**). JH acid is also detected in the hemolymph of *M. sexta* (Baker *et al.*, 1987) and of the silkworm *Bombyx mori*, where, at certain critical stages, the titer of JH acid surpasses that of JH (Niimi and Sakurai, 1997). JH acid is found as a product of the CA in other lepidopterans including the adult male loreyi leafworm, *Mythimna loreyi* (Ho *et al.*, 1995a, 1995b), the adult male black cutworm, *Agrotis ipsilon* (Duportets *et al.*, 1998), and the larval tomato moth, *Lacanobia oleracea* (Audsley *et al.*, 2000).

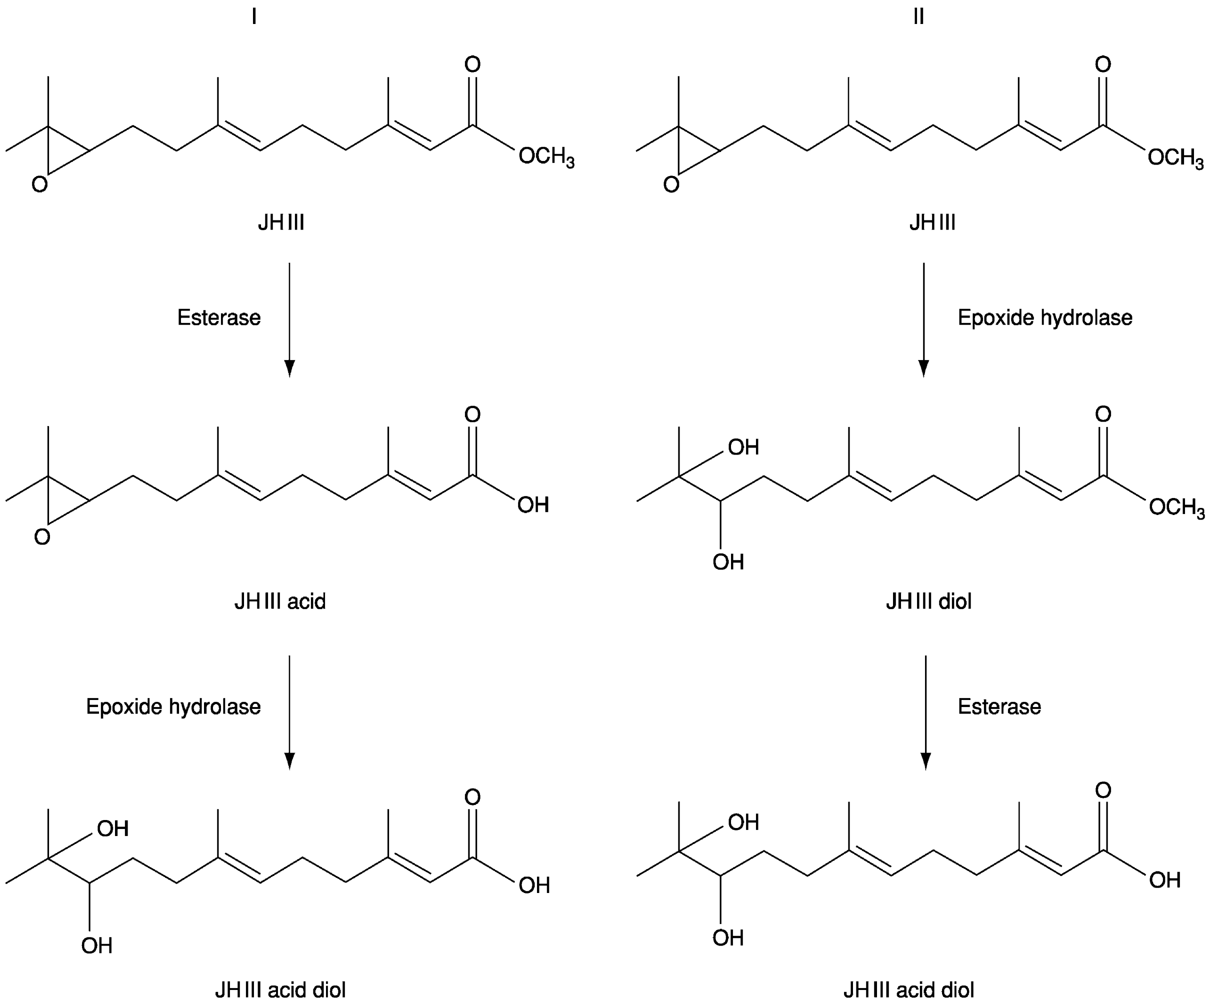

Figure 2 Primary routes of JH metabolism. Route I represents hydrolysis of the methyl ester via an esterase followed by hydrolysis of the epoxide ring via an epoxide hydrolase. Route II represents hydrolysis of the epoxide ring via an epoxide hydrolase followed by hydrolysis of the methyl ester via an esterase. The end product in both routes is JH acid diol.

Studies by Bhaskaran and his colleagues suggest that JH acid may be a hormone in its own right. The ability of *M. sexta* fat body cells to respond to the JH analog methoprene (**Figure 1**) with enhanced production of yolk protein and its mRNA is acquired after ecdysteroid-initiated commitment to pupation, but it also requires prior exposure to JH II acid or methoprene acid (Ismail *et al*., 1998). In subsequent work, Ismail *et al*. (2000) demonstrated that for two metamorphic events, the production of pupal proteins by Verson's gland, and the loss of the ability of crochet epidermis to produce larval crochets, exposure to JH acid or methoprene acid plus a low dose of RH5992 (an ecdysteroid analog) is required. Use of RH5992 or methoprene acid alone does not induce these changes. Gilbert *et al*. (2000) recently outlined unpublished experiments by Bhaskaran and colleagues to determine whether JH acids played a role in the acquisition of metamorphic competence in abdominal rings of first stadium *D. melanogaster*. Preliminary results indicate that JH acid plus ecdysteroid induce in first instar *D. melanogaster* both Broad, a transcription factor that appears in response to ecdysteroids early in the last larval stadium (see Section 3.7.12.3), and the adult promoter of alcohol dehydrogenase. However, attempts to repeat this work have been inconclusive, and the results of the previous works have been questioned on technical grounds.

3.7.3.2. Other Juvenile Hormones

It is a curious fact that the JH of *Rhodnius prolixus*, the hemipteran used by Wigglesworth in his pioneering experiments on the nature of the hormones controlling growth and reproduction (Wigglesworth, 1936), does not correspond to any other known JH (Wyatt and Davey, 1996). Early

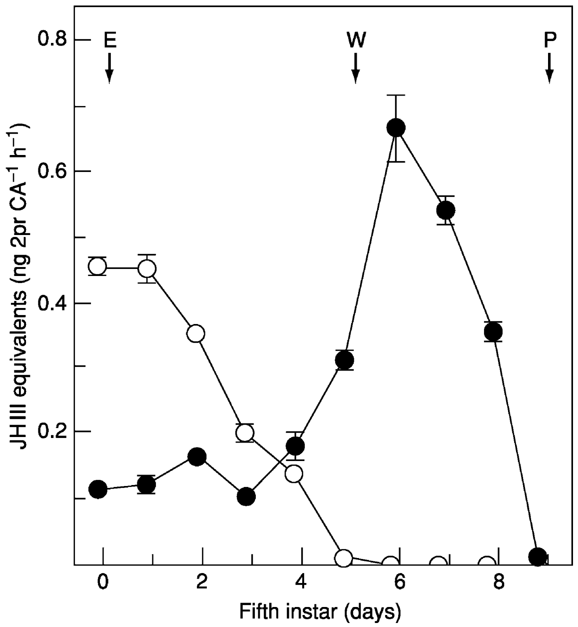

Figure 3 Biosynthesis of JH and JH acid by *Manduca sexta* corpora allata (CA) *in vitro*. Biosynthesis of JH I (open circles) and JH I acid (closed circles) by CA *in vitro* from fifth instars as measured by radioimmunoassay after separation of JH and JH acid by phase partition. Synthesis is expressed as ng JH I radioimmunoassay equivalents. E, the time of larval ecdysis; W, the onset of wandering behavior; P, the time of pupal ecdysis. Each datum point is the mean of 9–12 incubations (±SEM). (Reproduced from Janzen, W.P., Menold, M., Granger, N.A., **1991**. Effects of endogenous esterases and an allatostatin on the products of *Manduca sexta* corpora allata *in vitro*. *Physiol. Entomol. 16*, 283–293.)

attempts to identify the hemipteran JHs did not meet with success (Baker *et al*., 1988), but a more recent report suggests that JH I is the JH of Hemiptera (Numata *et al*., 1992). Unfortunately, this latter identification seems doubtful in light of the results of Kotaki (1993, 1996). These studies revealed that while the product of the CA of the stink bug, *Plautia stali*, has a sesquiterpenoid skeleton similar to JH III, the addition of the JH III precursors farnesoic acid or farnesol to incubations of CA stimulates the production of neither JH III nor JHB_3, but one that differs chromatographically from any known JH (Kotaki, 1997).

Among the possible groups of known, but nontraditional JHs, are the biosynthetic precursors of JH (**Figures 4** and **5**). Methyl farnesoate (MF) (**Figure 1**) may be the crustacean form of the insect JH (see Section 3.7.6; **Chapter 3.16**), but it is also present during embryogenesis in the cockroach *Nauphoeta cinerea* (Bürgin and Lanzrein, 1988) (see Section 3.7.10.2) and is synthesized by the embryonic CA of *D. punctata* (Cusson *et al*., 1991a) and the adult CA of the dipteran *Phormia regina* (Yin *et al*., 1995). In *P. regina*, MF alone has limited JH-like biological activity, but appears to work best in a coordinated role together with JH III and JHB_3.

Farnesoic acid (FA) (**Figure 4**), another JH precursor, has also been identified as a product of the *D. punctata* nymphal CA; moreover, it is proposed to have a hormonal or prohormonal function during the latter half of the fourth stadium, when release of JH III ceases. Alternatively, it may be secreted as a by-product of *O*-methyl transferase activity in the terminal steps of JH III biosynthesis (Yagi *et al*., 1991). Cusson *et al*. (1991a) speculate that continued synthesis of FA would allow for the rapid resumption of JH III synthesis when it is needed.

Plants possess compounds that exhibit JH-like activity in insect bioassays, and these molecules are considered to play a defensive role. For the most part, these "phytojuvenoids" are structurally distinct from the insect JHs and, with the exception of farnesol, which occurs widely in flowering plants, do not resemble the JH homologs (Bergamasco and Horn, 1983). Curiously, (10*R*)-JH III and MF have been conclusively identified in the sedges *Cyperus iria* and *C. aromaticus* (Toong *et al*., 1988). Recently, it has been possible to produce JH III and its precursors and to define its biosynthetic pathway in cell suspension cultures of *C. iria* (Bede *et al*., 1999, 2001). Given the large amount of JH III present in the plants, one might suspect that it acts as a naturally occurring insect growth regulator to deter feeding. However, it is possible that the plant uses the hormone as a plant growth inhibitor to retard the growth of other nearby species.

There exist a few compounds with no structural similarity to the JHs that display hormonal activity. The ecdysteroids top this short list. Ovarian ecdysteroids have long been known to have JH functions in adult females, stimulating the synthesis of vitellogenin in some species, and terminating previtellogenic reproductive diapause and promoting uptake of yolk proteins by oocytes in others, all roles traditionally associated with JH (Hagedorn, 1983; Girardie and Girardie, 1996; Richard *et al*., 1998) (see **Chapter 3.9**). There may also exist peptides that mimic the action of JH. In *R. prolixus*, JH stimulates protein synthesis in the male accessory gland *in vitro*, a function also supported by an uncharacterized neuropeptide from the brain (Barker and Davey, 1983; Gold and Davey, 1989). In addition, there are reports of peptides stimulating the synthesis of vitellogenin in *L. migratoria*, a role usually attributed to JH (Girardie and Girardie, 1996; Girardie *et al*., 1998). Finally, there is the proposal of Davey (2000b) that thyroid hormones may function

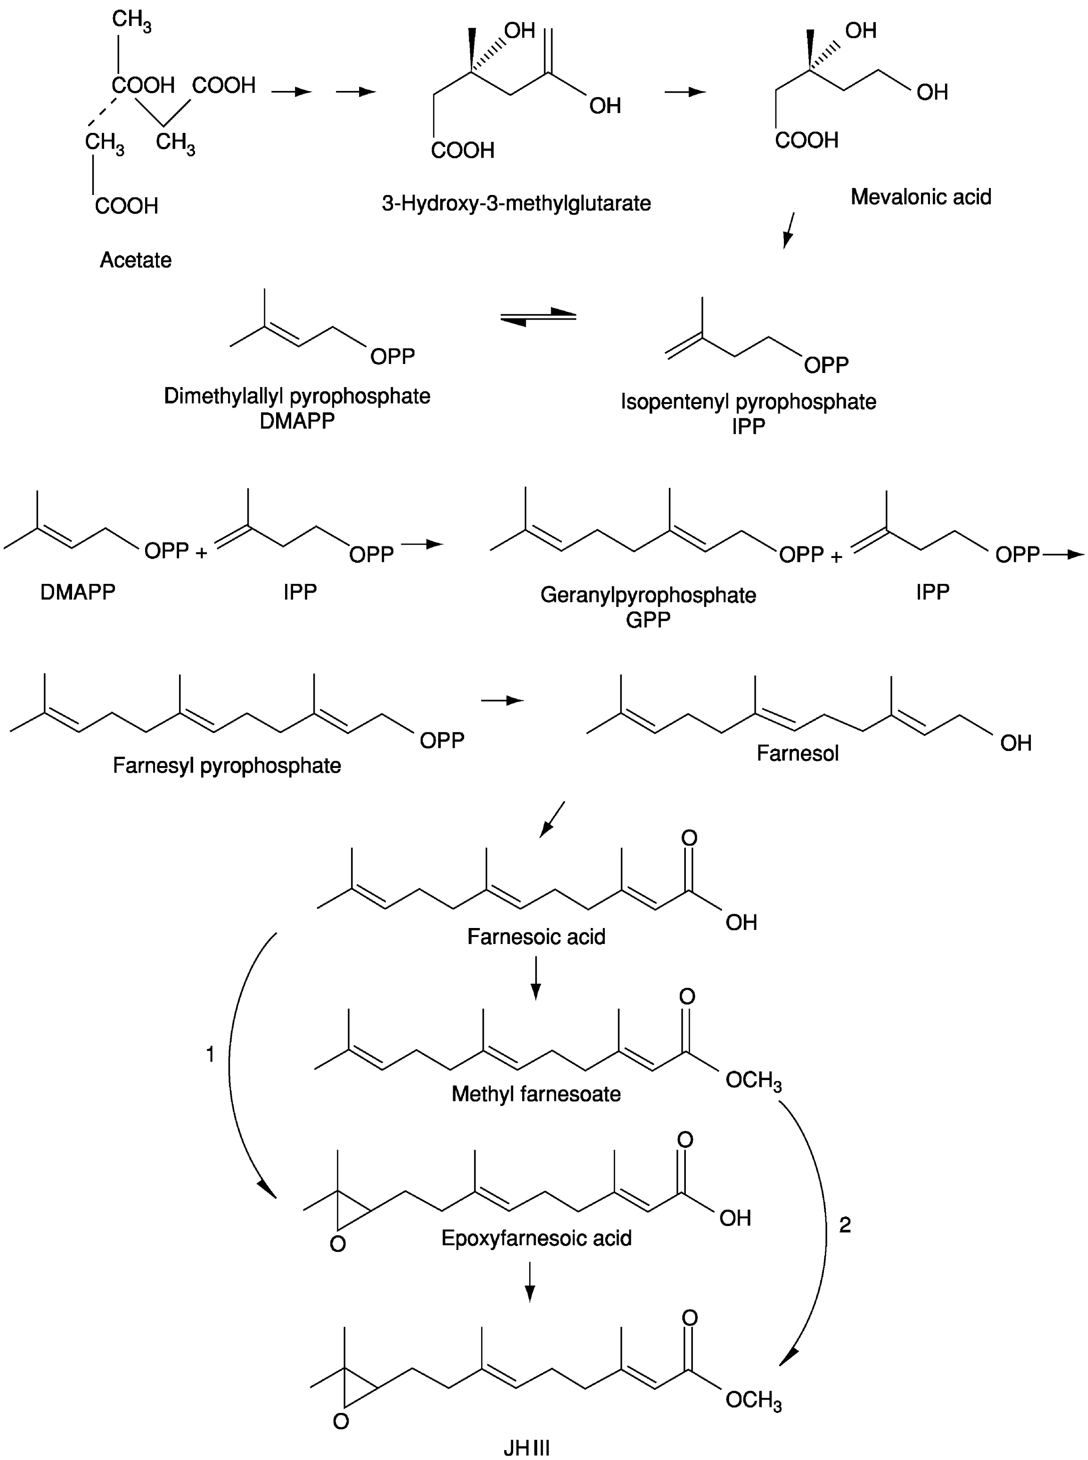

Figure 4 Biosynthetic pathway for JH III. In Lepidoptera, the last two steps in the biosynthetic pathway convert farnesoic acid to JH acid, which is then methylated to form JH III (**1**). In Orthoptera and Dictyoptera, the last two steps in the biosynthetic pathway convert farnesoic acid to methyl farnesoate, which is then epoxidized to form JH III (**2**).

in insects. Phenoxy-phenyl compounds such the JH analog fenoxycarb (Figure 1), thyroxine (T4) and triiodothyronine (T3) mimic the effects of JH III in reducing the volume of follicle cells in *L. migratoria* (Davey and Gordon, 1996; Kim *et al.*, 1999). In many species, follicle cells respond to JH by altering their cytoskeletal structure, resulting in the appearance of lateral spaces between the cells (patency) via which vitellogenin gains access to the oocyte surface (Davey *et al.*, 1993). T3 binds to the same receptor

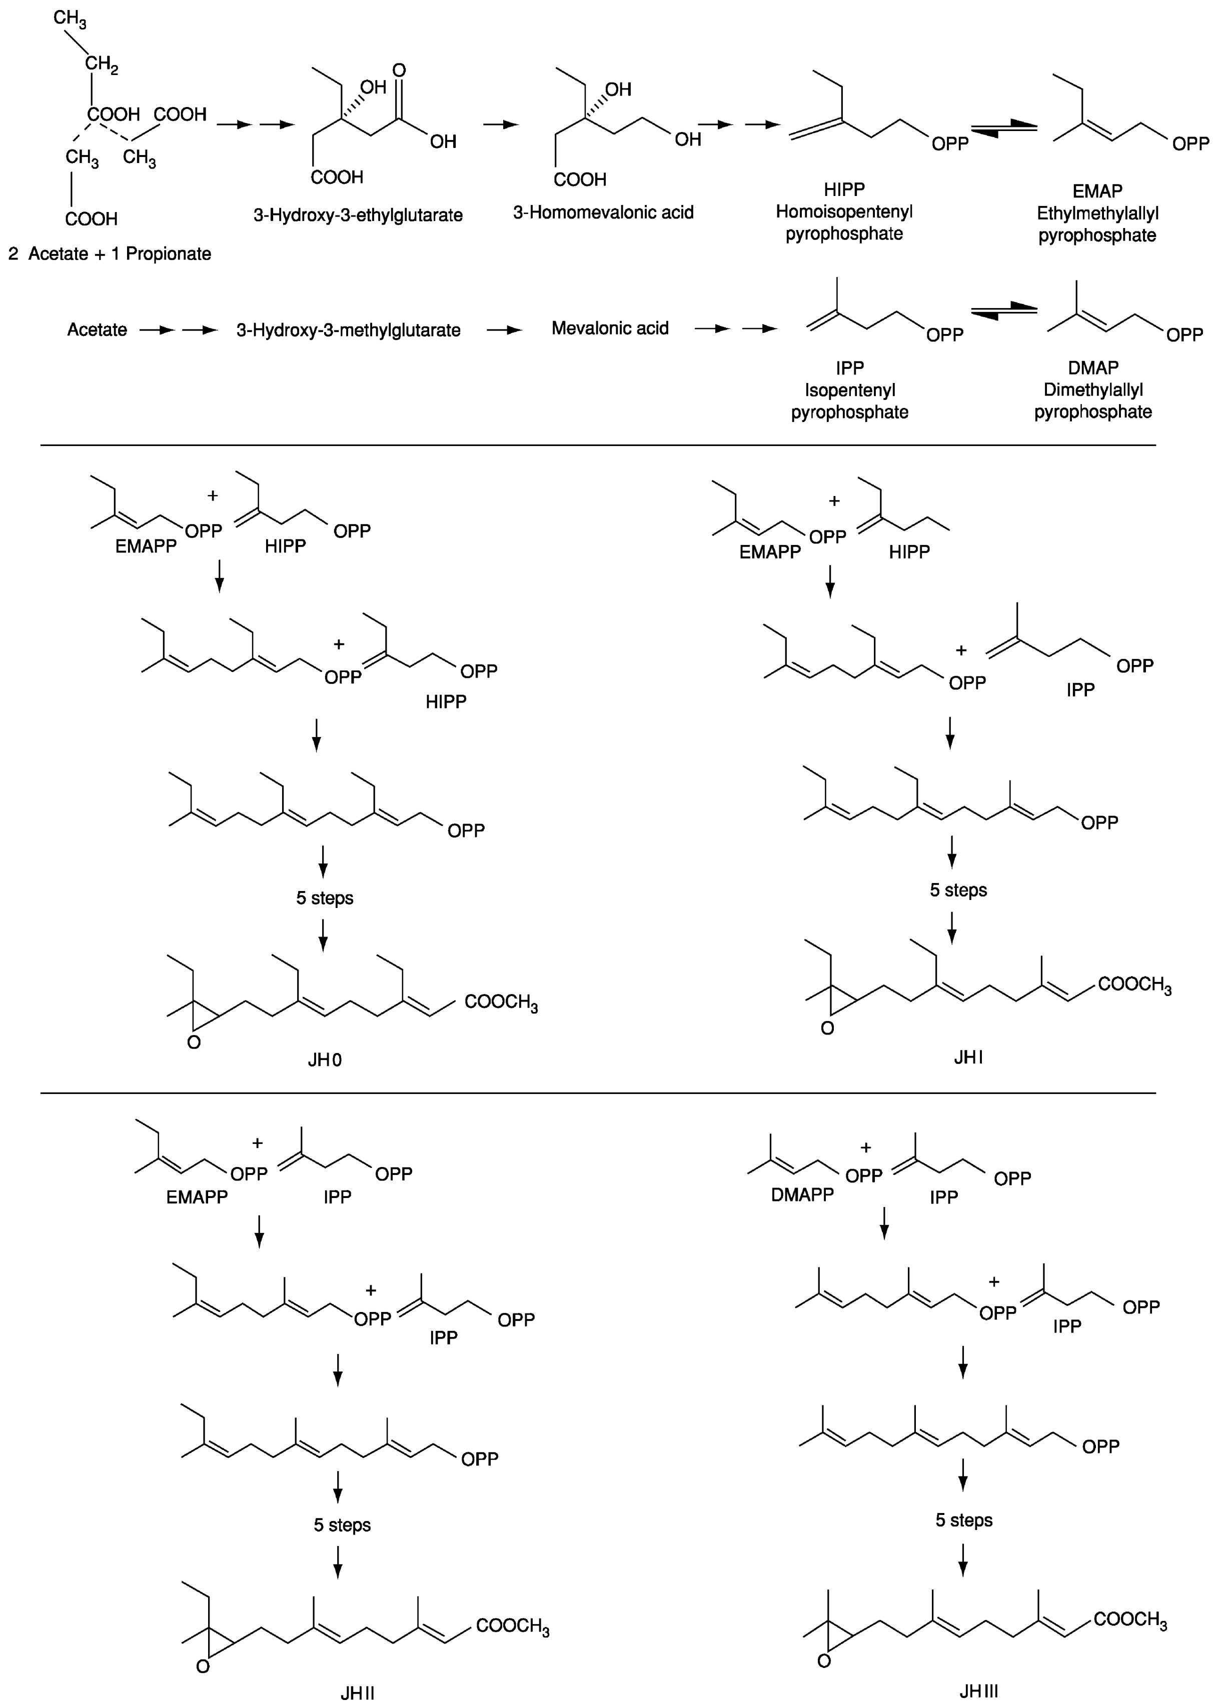

Figure 5 Biosynthetic pathways for JH 0, I, II, and III.

on locust follicle cells as JH III (Davey and Gordon, 1996; Kim *et al*., 1999), and T3 immunoreactivity can be found in locust hemolymph (Davey, 2000a, 2000b). Locust food (wheat shoots and bran) was found to contain both T3 and T4, thus suggesting that insect diets could serve as supplementary sources of compounds which act as JH (Davey, 2000b). The fact that T3 apparently binds to a receptor that also binds JH has interesting implications in the search for potential JH receptor(s) (see Section 3.7.12).

The increased sensitivity afforded by modern analytical tools should make easier the difficult task of deciphering the biological roles of these new JH-like molecules. Are they biologically relevant or are they the result of promiscuous biochemical reactions that yield end products with no real biological activity? It remains to be determined whether the results of studies using incubations *in vitro* or homogenates of CA to generate new JH-like molecules under experimental conditions bear any resemblance to the situation *in vivo*. There is good evidence from vertebrate endocrinology to believe that it is a real problem. A very early study on corticosteroid biosynthesis in the adrenal gland (Heftmann and Mosettig, 1960) lists more than 40 corticosteroids present in the human adrenal glands, even with the limited technology of that time. Of those, only a handful have ever been detected in the blood. A similar situation has been found with the insect ecdysteroids (Rees, 1985) (see **Chapter 3.3**).

3.7.4. Biosynthetic Pathways for the Juvenile Hormones

The biosynthetic pathway for the JHs, now known for many years, has been described in exquisite detail by Schooley and Baker (1985). Briefly, biosynthesis of the most ubiquitous JH, JH III, proceeds by the normal terpenoid pathway: the formation of five-carbon (5C) isoprenoid units from acetate via mevalonic acid, with the sequential head to tail condensation of three 5C units to form farnesyl pyrophosphate (**Figure 4**). Farnesyl pyrophosphate then undergoes esteratic cleavage to farnesol, which is then oxidized to FA. The last two steps in the biosynthetic pathway diverge depending upon the insect order. In Lepidoptera, a C10,C11 epoxidase converts the FA to the epoxy acid (JH acid), which is then methylated by an *O*-methyl transferase to form the methyl ester. In Orthoptera and Dictyoptera, the converse appears to be the case: epoxidation follows methylation (Schooley and Baker, 1985; **Figure 4**).

Synthesis of the higher homologs, JH 0, I, and II, appears to be a unique biochemical feature limited to certain insect species (Schooley *et al*., 1984). These insects can synthesize homoisoprenoid (6C) units from acetate and propionate via 3′-homomevalonate, and from a mixture of these isoprenoid (5C) and homoisoprenoid (6C) units form the respective homologs (**Figure 5**). Thus, three homoisoprenoid units (ethylmethylallyl pyrophosphates) form the skeleton of JH 0, two homoisoprenoid units and one isoprenoid unit (dimethylallyl pyrophosphate) form JH I, and one homoisoprenoid unit and two isoprenoid units form JH II.

With regard to the pathway for JHB_3, Moshitzky and Applebaum (1995) have presented evidence that synthesis in *D. melanogaster* proceeds from FA, which is epoxidized twice, at C6,C7 and C10, C11 to form 6,7;10,11-bisepoxyfarnesoic acid (FABE). FABE is then methylated to yield JHB_3 (**Figure 6**). It should be noted that JH III is not epoxidized to JHB_3.

3.7.4.1. Specificity of the Biosynthetic Pathways

The coexistence of multiple JH homologs in a single species at the same developmental stage, together with the discovery of new forms of JH in insects previously thought to have only one, presents an enigma not only as to their functions, but also as to the substrate specificity of the pathways by which they are synthesized and the regulatory mechanisms that effect those steps. Schooley and Baker (1985) concluded that biogenesis of the JH skeleton occurs via the condensation of isoprenoid and homoisoprenoid units and that overwhelming evidence suggests low substrate specificity at most steps in the biosynthetic pathway, even in enzyme preparations from CA, or incubations of CA, from insects known to produce JH III only. This is particularly evident in the two terminal steps, where lack of substrate specificity has been demonstrated in a number of species. For example, the CA of the locust *Schistocerca gregaria*, which normally synthesize only JH III *in vitro*, will produce JH I as their sole product if incubated with dihomofarnesoic acid (Schooley *et al*., 1978a). Schooley and Baker (1985) concluded that the proportions of the precursors (propionate, mevalonate, and homomevalonate) added to incubation medium in which CA are maintained dictate the proportions of the JH homologs produced.

The precursor propionate is essential for the formation of the ethyl side chain of JH 0, I and II (**Figure 5**), and within the CA, propionate is derived principally from the branched-chain amino acids

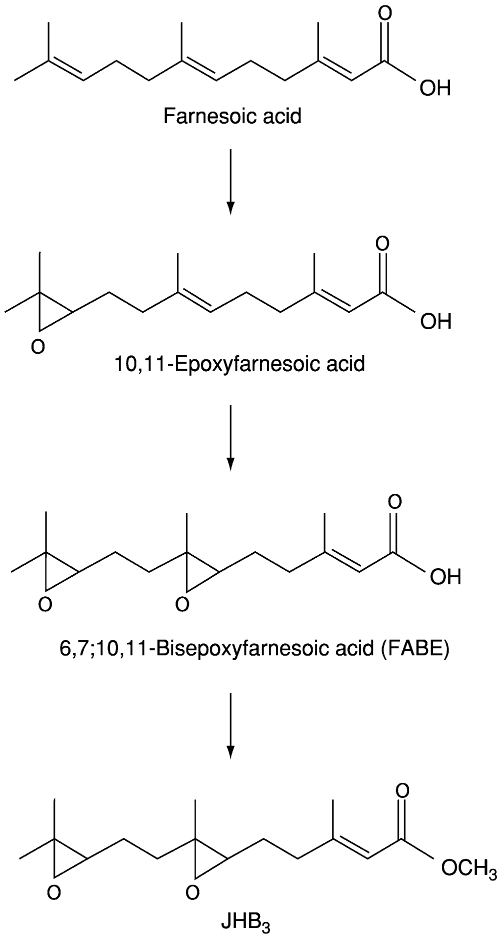

Figure 6 Biosynthetic pathway for JHB_3.

isoleucine and valine (Brindle *et al.*, 1988). The CA of *D. punctata* produce only trace amounts of JH II *in vitro* when propionate is the sole carbon donor, while continuing to produce copious amounts of JH III, the sole naturally occurring JH in this species (Feyereisen and Farnsworth, 1988). The CA of such insects are unable to convert branched-chain amino acids into propionate due to the lack of an active branched-chain amino acid transaminase (Brindle *et al.*, 1987, 1992). Cusson *et al.* (1996) tested the hypothesis that shifts in the proportions of the different JHs and JH acids released by lepidopteran CA are associated with changes in the activity of the transaminase. They found that the age-related increase in the biosynthesis of JH I acid by adult male CA of the moth *Pseudaletia unipuncta* was linked to an age-related increase in transaminase activity in CA homogenates. This increase was not observed with female CA, which synthesized more JH II than JH I during this same time period. The authors propose the existence of a factor regulating propionate production in lepidopteran CA. This factor is not the *M. sexta* allatostatin (see Section 3.7.7.2) that inhibits JH biosynthesis by female *P. unipuncta* CA, since this peptide has no effect on the rate of isoleucine metabolism by either male of female glands.

Thus, as predicted, the availability of propionate within the CA and the activity of the transaminase has a significant impact on the proportions of JH I and II and their acids, but has no effect on the production of JH III, which is synthesized from the nonbranched isoprenoid units (**Figure 5**). The specificity and activity of other enzymes may therefore be involved in creating the blend of JH homologs and their acids synthesized by lepidopteran CA. As noted by Schooley *et al.* (1976) and Cusson *et al.* (1996), these enzymes may be the isopentenyl diphosphate isomerase and the farnesyl diphosphate synthase that catalyze the condensation of the isoprenoid and homoisoprenoid units to form the backbone of the JH homologs. Due to their low abundance, the substrate specificity of these enzymes has not been studied in enzyme preparations from CA homogenates. The cloning and sequencing of farnesyl diphosphate synthase in *A. ipsilon* (GenBank Accession no. AJ009962) and *B. mori* (GenBank Accession no. AB072589) have been reported (Castillo-Gracia and Couillaud, 1999; Kikuchi *et al.*, 2001), and recently Sen and Sperry (2002) have partially purified native farnesyl diphosphate synthase from whole-body preparations of *M. sexta*. Thus, substrate specificity for this enzyme may be known in the near future.

Sen and her colleagues have also examined other enzymes in the JH biosynthetic pathway, including the specificity of prenyltranferase activity of the larval CA of *M. sexta* (Sen and Ewing, 1997). This enzyme catalyzes the head-to-tail condensation of dimethylallyl diphosphate (DMAPP) and isopentenyl diphosphate (IPP) units to form the skeleton of JH III, and of homoisopentenyl phosphate and ethylmethylallyl diphosphate (EMAPP) to form the skeletons of JH 0, I, II and 4-methyl JH I (**Figures 5** and **6**). Using homodimethylallyl diphosphate (HDMAPP) and the natural and unnatural homologs of geranyl diphosphate (GPP) (formed from the first coupling of one DMAPP and one IPP in the synthesis of JH III) (**Figure 5**), they found that this enzyme has a high tolerance for homologous substrates. EMAPP was a better substrate than DMAPP, while the unnatural geranyl homolog was a poorer substrate for the prenyltransferase than the natural homolog, suggesting that this enzyme contributes to the specificity of the JH skeleton.

Sen and Garvin (1995) examined the specificity of the farnesol dehydrogenase, an enzyme that

catalyzes the oxidation of farnesol to farnesal. Their results suggest that this enzyme is a unique dehydrogenase with high specificity for alcohols with Δ-2,3 unsaturation and alkyl chain hydrophobicity corresponding to at least three isoprenoid units, and hence is a selective enzyme for JH biosynthesis. In a subsequent study, Sperry and Sen (2001) concluded that, in fact, the oxidation of farnesol to farnesal did not involve a unique dehydrogenase, but rather a specific oxygen-dependent enzyme, possibly a flavin- or nonheme iron-dependent oxidase. Further studies on these enzymes will identify targets for compounds with anti-JH activity, as well as foster a better understanding of the key enzymes that are targets of allatotropins and allatostatins (see Section 3.7.7).

3.7.4.2. Possible Feedback Loops in the Biosynthetic Pathways

The formation of farnesyl pyrophosphate is an intermediate step in the synthesis of JH from mevalonate. A mammalian "orphan" nuclear receptor activated by farnesyl pyrophosphate metabolites has been identified (Forman *et al.*, 1995) and termed farnesoid X receptor (FXR) (Weinberger, 1996). FXR is activated by farnesol, farnesal, FA, and methyl farnesoate (**Figure 4**), and is expressed in isoprenoidogenic tissues. It has been suggested that these farnesyl pyrophosphate metabolites (farnesoids) may be signals for transcriptional feedback control of cholesterol biosynthesis, since cholesterol is synthesized from isoprenoids (Weinberger, 1996). As noted by Gilbert *et al.* (2000), Weinberger and his colleagues used a transactivation assay in Chinese hamster ovary cells by transfecting with plasmid DNAs expressing FXR, RXR (retinoid X receptor) and a farnesol responsive chloramphenicol acetyltransferase (CAT) reporter to demonstrate that JH, methoprene, and farnesol can all affect mammalian FXR. Farnesoids are JH biosynthetic agonists; they stimulate the formation of JH when added to incubations of CA and are derived from farnesyl pyrophosphate by a metabolic pathway that may serve to excrete surplus isoprenoid precursors (Schooley and Baker, 1985). Since insects cannot synthesize cholesterol *de novo* and require a dietary source of sterols (Rees, 1985), FXR may be involved in the feedback control of JH biosynthesis via these farnesoids. This possibility certainly deserves further study and opens the door to an exciting field of investigation of the role of orphan nuclear receptors in the regulation of JH biosynthesis (Chawla *et al.*, 2001) (see Section 3.7.7.3)

3.7.4.3. What Constitutes a Juvenile Hormone Titer?

As discussed by Darrouzet *et al.* (1998), the identification of new JHs, whether metabolites, conjugates, precursors, or hydroxylated forms, illustrates the variability of compounds released as end products from the CA; these end products are what Darrouzet *et al.* (1998) term "bouquets" of compounds. The "bouquets" are different in different orders, and undoubtedly vary between species within orders, and even within species by sex and stage in the life cycle (Couillaud, 1995). This is certainly true for *M. sexta*, where JH I, II, and III and their acids have been measured in larval hemolymph (Baker *et al.*, 1987), and for *P. regina*, in which the CA secrete JH III, JHB_3, and MF (Yin *et al.*, 1995). Thus, it may be naive to think of the circulating titer of a single JH as responsible for the production of a JH effect. Rather, it may be a particular ratio or balance of homologs that is important for biological activity.

Sites outside the CA may also contribute to the circulating titers of the different hormones by metabolism, catabolism, hydroxylation, or conjugation. The JH I originally isolated and identified from the abdomens of male *H. cecropia* pupae (Röller *et al.*, 1967) was, in fact, synthesized by male accessory glands from JH acid secreted by the CA (Dahm *et al.*, 1976; Peter *et al.*, 1981). The male accessory glands in the mosquito *Aedes aegypti* synthesizes JH I, JH III, JHB_3, and MF from acetate (Borovsky *et al.*, 1994a), and the mosquito ovary synthesizes JH III from FA (Borovsky *et al.*, 1994b). Non-JHs such as the thyroid hormones, which can be ingested by the insect, may function as a JH in some JH-linked events. Are we safe in assuming that an event is truly JH independent if it occurs in an insect from which the CA have been removed (Davey, 2000a)? Is the JH titer in the hemolymph truly reflective of what elicits a JH-dependent event?

Thus, in considering JH titers and any temporally linked JH-dependent event, the event must be viewed from the perspective of a coordinated interplay between products of the CA, the products of other tissues in the body, the catabolism of these products (see Section 3.7.9), and the receptors for these products on the target tissues (see Section 3.7.12.1). The list of products possibly involved in this interplay is long and getting longer.

3.7.5. Measurement of the Juvenile Hormones

The lipophilic nature of JH, its occurrence in exceptionally low concentrations in biological samples

(parts per billion or lower), its lability, and its tendencies to bind nonspecifically to substrates, contribute to making this one of the most difficult of all hormones to measure accurately. There are three methods employed to quantitatively assess JH titers: bioassays, physicochemical assays, and radioimmunoassays. Relative JH titers can be determined using the radiochemical assay.

3.7.5.1. Bioassays

The first techniques used to measure JH titers were an assortment of bioassays that quantified a JH effect on a morphological or physiological process (Sláma *et al.*, 1974). Initially, these bioassays were used to assess the activity of transplanted CA, but are now more commonly used to quantify JH indirectly by comparing the biological response of an unknown preparation to a known amount of JH. These types of assays have been well described and critiqued in previous reviews (Feyereisen, 1985; Baker, 1990). Their use is in decline for a number of reasons: (1) they are cumbersome; (2) they are time-consuming, requiring maintenance of a test insect colony; (3) they are subjective in their scoring; (4) they lack specificity, because they measure only total JH; and (5) they show differential sensitivity to the various homologs. Nevertheless, several assays including the *Galleria* wax test (Gilbert and Schneiderman, 1961; deWilde *et al.*, 1968) and the *Manduca black* larval assay (Fain and Riddiford, 1975) are still used, since there are certain instances where bioassays play an important role. These include testing biological extracts for JH activity, especially when the active ingredient is thought to have a non-JH-like structure, or monitoring biological activity of a JH during its purification process.

3.7.5.2. Physicochemical Assays

With growing sophistication in the technology for studying organic compounds, a number of physicochemical methods have been developed for measuring JH in biological samples. Unfortunately, none of these methods is rapid, simple, or inexpensive. Moreover, the literature surrounding the physicochemical detection methods is awash in methods that can be bewildering for a biologist. The current physicochemical methods reflect several decades of experimentation that emphasized specificity and ultrasensitivity at the expense of simplicity. There are normally two phases to the physicochemical assay; the sample extraction/clean-up phase, and the quantification phase. Because JH represents only a minute fraction of the extractable lipids, especially in whole-body extracts, protocols generally require some type of clean-up procedure(s) such as column chromatography, thin layer chromatography, separatory cartridge purification, HPLC, and/or gas chromatography (GC). Preparation of a biological sample for JH analysis has been discussed in several excellent reviews that cover extraction methods, solvents, and partition techniques (Baker, 1990; Halarnkar and Schooley, 1990). Further cautions with regard to degradation, volatility, and nonspecific adsorption have also been extensively outlined (Granger and Goodman, 1983, 1988; Goodman *et al.*, 1995).

Once the clean-up procedure is completed, JH can be quantified by a number of different procedures that employ a gas chromatograph interfaced with an electron-capture detection unit or mass spectrometer (Baker, 1990). In the early analyses of the hormones, GC separation of underivatized JH was coupled with electron impact (EI) or chemical ionization (CI) detection systems to monitor levels of the hormone. While these methods required no derivatization, they often resulted in complex spectra, poor recoveries, and an accumulation of breakdown products (Baker, 1990). Moreover, JH is not particularly stable under most GC conditions, due to instability of the epoxide ring. The use of CI, with its softer ionization process and its improved sensitivity and specificity, yields fewer fragment ions than the harsher EI ionization mode. Nevertheless, problems remain with the misidentification of the JH homologs (Baker, 1990).

To enhance sensitivity and specificity, methods were developed that generated JH derivatives with unique chemical tags. The first to be developed were the organohalide derivatives that are detected by a GC interfaced with an electron capture detection (ECD) system. While this method greatly increased sensitivity of the assay, it had serious drawbacks in uniformity of derivatization and in identification of the homologs. To overcome these difficulties, Rembold *et al.* (1980) and Bergot *et al.* (1981b) developed GC-mass spectrometry (MS) methods which, while still requiring derivatization of the hormones, were far more efficient and sufficiently selective to allow each JH homolog to be identified using selected ion monitoring. GC-MS-EI and GC-MS-CI analyses are now performed with slight variations on these procedures (Neese *et al.*, 2000; Smith *et al.*, 2000; Cole *et al.*, 2002).

Teal *et al.* (2000) have recently developed a method for quantifying JH from biological samples that allows for direct analysis of hormone without derivatization. These investigators use GC interfaced with ion-trap MS and CI. This method

requires no clean-up procedure or sample derivatization and is highly sensitive, and thus may be the assay of choice for future studies. While this procedure has been used to titer JH in hemolymph (Burns *et al.*, 2002) and culture medium (Bede *et al.*, 2001), in which lipid content is relatively low, it will be interesting to see if the assay can be successfully used with whole-body extracts.

The advantage of the physicochemical assays lies in their sensitivity and their unequivocal identification of the different JHs and metabolites. Their drawback lies in accessibility to the prohibitively costly equipment and the relatively low throughput.

3.7.5.3. Radioimmunoassays

Radioimmunoassays (RIAs) are a rapid, sensitive, and inexpensive alternative to measuring JH, both in biological samples and in medium from incubations of CA. The JH RIA is a competitive protein binding assay in which JH from a biological sample competes with a fixed amount of radiolabeled JH for a limited number of binding sites on JH-directed antibodies. The radiolabeled JH bound to the antibody in the presence of the unknown is compared to a standard curve derived with known amounts of radioinert JH.

Since JH itself is not antigenic, antibodies against JH are produced by chemically linking JH to a protein such as human serum albumin or thyroglobulin. The hormone can be conjugated to the protein via the C1 (ester) terminus of JH or through C10,C11 (see Granger and Goodman, 1983, 1988; Baker, 1990; Goodman, 1990, for reviews of the technique). The resulting antiserum is carefully screened for specificity, since it may recognize a particular JH homolog exclusively (Granger *et al.*, 1979, 1982; Goodman, 1990), two or more homologs to differing extents (Granger and Goodman, unpublished data), or all homologs equivalently (Goodman *et al.*, 1993, 1995).

Like the physicochemical methods, JH from whole-body or hemolymph extracts must be partially purified prior to conducting the RIA. The partial purification process is essential for a successful assay since a number of lipids can nonspecifically interfere with the assay. Inattention to this process invariably results in excessively large and inaccurate JH titers due to micelle formation of nonspecific lipids that either trap JH or inactivate the JH-directed antibodies. Misidentification of the JH homologs and overestimation of titers can also occur when chromatographic systems contaminated with high levels of JH standards are also used for the purification of biological samples (Baker *et al.*, 1984). It is for these reasons that RIA technology has rightly been criticized (Feyereisen, 1985; Tobe and Stay, 1985). A number of excellent clean-up procedures have been suggested (Strambi, 1981; Strambi *et al.*, 1981; Goodman *et al.*, 1995; Niimi and Sakurai, 1997; Noriega *et al.*, 2001). It is important to note that despite differences in extraction methods and JH-directed antibodies, excellent agreement between assays can be achieved (Goodman *et al.*, 1993).

JH RIAs have been used most effectively to measure CA activity *in vitro*, since the products are secreted into defined incubation medium that lacks the massive amount of lipid found in whole-body or hemolymph extracts. RIAs have been used extensively in studies on CA activity and in control of JH biosynthesis in the tobacco hornworm (Bollenbacher *et al.*, 1987; Granger and Janzen, 1987; Janzen *et al.*, 1991; Granger *et al.*, 1994), locusts (Couillaud *et al.*, 1984; Baehr *et al.*, 1986), honeybees (Huang and Robinson, 1995), and bumblebees (Cnaani *et al.*, 2000). Furthermore, certain extant RIAs recognize JH and JH acid equivalently (Janzen *et al.*, 1991), which can be a benefit in light of the fact that the CA of a number of species secrete JH acid at certain times in their life cycle (Sparagana *et al.*, 1984; Janzen *et al.*, 1991; Ho *et al.*, 1995a, 1995b; Niimi and Sakurai, 1997; Duportets *et al.*, 1998; Audsley *et al.*, 2000).

One of the major problems that has plagued research on the chemistry and biology of JH is the lack of commercially available, enantiomerically pure JH; nowhere is this more evident than in RIA technology. Depending upon the antigen used for immunization and immunocompetence of the rabbit, antibodies can be highly specific and capable of recognizing a single enantiomer of each homolog. Thus, using racemic JH as a standard may pose difficulties in establishing an accurate titer. A very complex binding reaction is generated when the radiotracer is racemic, but JH from the biological sample is enantiomerically pure; the analysis becomes even more complex when the radioinert standards are racemic. This problem has been eliminated by the use of a chiral HPLC matrix that can resolve the JH enantiomers (Cusson *et al.*, 1997). Moreover, the use of the appropriate enantiomers leads to increased sensitivity of the assay. Based on the ED_{50} values (effective dose required to inhibit binding of 50% of the radiolabeled tracer), the naturally occurring enantiomers of JH I, JH II, and JH III in this study were between 30 and 87 times more immunoreactive than the unnatural isomers. In summary, the JH RIA is a relatively rapid, inexpensive, and accurate method for titering JH. If

measurement of more than one homolog is required, then confirmation by physicochemical methods is recommended.

3.7.5.4. Radiochemical Assays

The radiochemical assay (RCA), originally developed by Pratt and Tobe (Pratt and Tobe, 1974; Tobe and Pratt, 1974), has been employed for many years to measure JH biosynthesis *in vitro* by the CA of a wide variety of insects (Feyereisen and Tobe, 1981; Tobe and Feyereisen, 1983; Tobe and Stay, 1985; Yagi and Tobe, 2001). The RCA measures the rate of incorporation of the methyl group from either [^{14}C]methyl methionine or [^{3}H]methyl methionine into JH in isolated CA. The availability of assay components, the relative simplicity of the protocol, its sensitivity (0.1 pmol), and the short incubation time (1–3 h), have made this assay popular among insect endocrinologists.

There is a general assumption that isolated glands lacking neural connections function in the same fashion as glands *in vivo*. This assumption has been challenged by Horseman *et al.* (1994), who demonstrated that nerve transection in adult *L. migratoria* led to a rapid, 16-fold increase in JH production. A similar result has also been found in isolated CA of *A. aegypti* (Noriega, personal communication). Thus, the RCA may, at certain times, seriously overestimate the expected *in vivo* production of JH (Pratt *et al.*, 1990). Another potential problem is the use of [^{3}H]methyl methionine as the methyl donor (Yagi and Tobe, 2001). The lack of definitive data from the manufacturers on the purity and specific activity of this compound can make determination of the biosynthesized JH difficult. Yagi and Tobe (2001) recommend either comparing incorporation of the [^{3}H]methyl group with the [^{14}C]methyl group in a dual-label experiment or switching altogether to [^{14}C]methyl methionine. It appears that isotopic discrimination by the *O*-methyl transferase leads to preferential incorporation of the [^{14}C]-labeled methyl group vs. the [^{3}H]-labeled methyl group, but only when concentrations of [^{3}H]methyl methionine above the normal range for the RCA are used.

The measurements of JH biosynthesis using the RCA can also be affected by the incubation medium, which in most instances is TC199. TC199 has a high $Na^{+}:K^{+}$ ratio (17.8) and thus is a suitable medium for the CA from insects where the hemolymph ratio of $Na^{+}:K^{+}$ is similar, for example, *Leptinotarsa decemlineata* or *T. molitor* (Granger *et al.*, 1986). This medium has been used extensively in the RCA, irrespective of insect species. For insects such as *M. sexta*, where the hemolymph $Na^{+}:K^{+}$ ratio is low (0.1) (Nowock and Gilbert, 1976), TC199 has been found to depress JH synthesis in comparison to Grace's medium, in which the $Na^{+}:K^{+}$ ratio is 0.33 (Granger *et al.*, 1986; Watson *et al.*, 1986). More recently, L-15B, a medium widely used in the culture of arthropod tissues and found to be isoosmotic with cockroach hemolymph, was demonstrated to be superior to TC199 for both long- and short-term cultures of cockroach CA (Holbrook *et al.*, 1997).

3.7.6. Evolution of the Juvenile Hormones

3.7.6.1. Juvenile Hormone Homolog Distribution among the Insect Orders

One or more of the JH homologs have been identified in nearly all species of insects in which they have been sought (Sehnal, 1984) and have even been found in Collembola, an order once thought basal to insects but now considered to represent a more ancestral group, distinct from insects (Nardi *et al.*, 2003). A JH effect on ecomorphosis of a collembolan species, *Hypogastrura tulbergi*, has been reported (Lauga-Reyrel, 1985), and on this basis, it seems likely that JH or a JH-like molecule functioned in the ancestors of modern insects at least 400 million years ago. **Figure 7** illustrates the evolutionary time line in which the various orders of insects were thought to have appeared, the orders in which JHs or JH-like molecules have been identified, and the identity of these compounds.

3.7.6.2. Evolutionary Connections among the Arthropods

Arthropods, which appeared more than 500 million years ago during the Cambrian period, include four extant classes: Hexapoda, Chelicerata, Myriapoda, and Crustacea. Of these, the Hexapoda and Crustacea appear to be the most closely related, based on molecular data, and are now considered together as Pancrustacea (Boore *et al.*, 1995; Friedrich and Tautz, 1995; Tobe and Bendena, 1999). **Figure 8** illustrates a time line of the appearance of the extant classes of Arthropoda and those classes in which JH effects have been demonstrated.

Outside the class Insecta, JH-like molecules have been identified in Crustacea (see **Chapter 3.16**), and functions for these molecules have been proposed. Both FA and MF, the immediate precursors of JH III (**Figure 4**), are major biosynthetic products of the mandibular organs of many crustaceans. The similarities in function and embryological origin of the

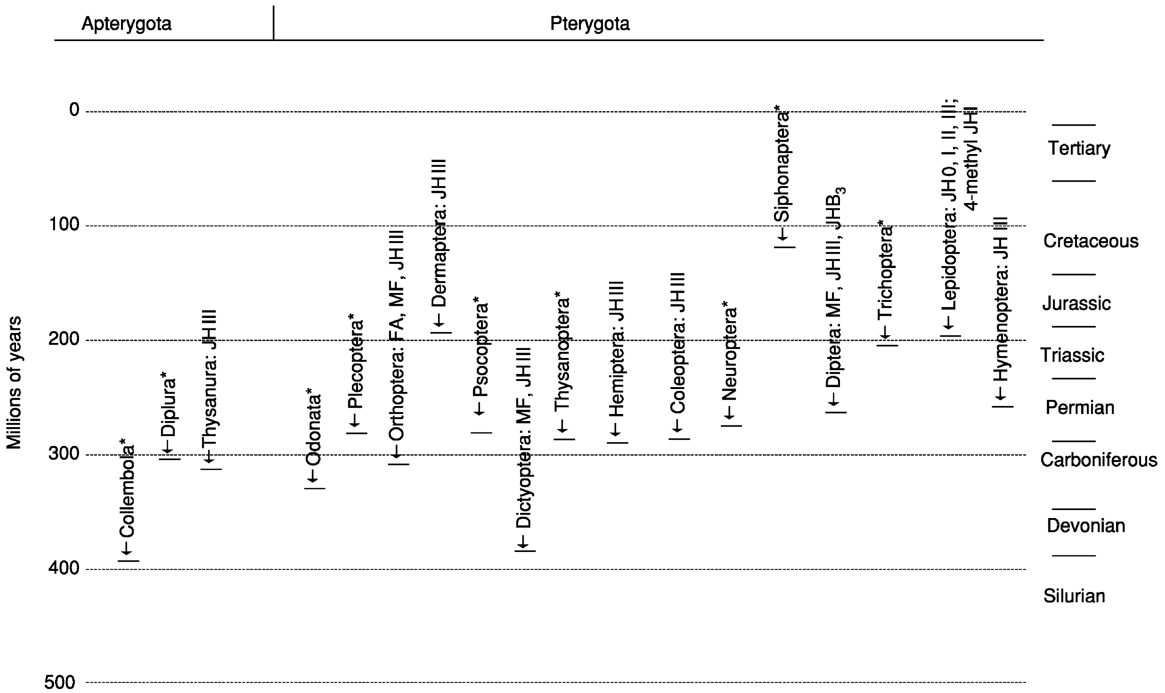

Figure 7 Evolutionary timeline for the appearance of the insect orders based on the earliest documented fossil record (Heming, 2003). Orders in which JH effects have been demonstrated are noted with an asterisk (*). Orders in which JH or JH-like molecules have been conclusively identified are noted by the homolog.

mandibular organs and CA, and the fact that the biosynthetic pathway for MF and FA are the same in both crustaceans and insects (see Section 3.7.4.1), suggests that these products may be the JHs of Crustacea. FA can act as a JH in crustacean reproduction (Laufer *et al.*, 1993), and MF has a juvenilizing role in the prawn (Abdu *et al.*, 1998) and the barnacle (Smith *et al.*, 2000) during metamorphosis from the larval to the juvenile form. MF also delays metamorphosis in larvae of the lobster, *Homerus americanus* (Borst *et al.*, 1987). Nevertheless, definitive physiological and developmental roles for these two JH precursors remain vague (Homola and Chang, 1997), and further work is needed to determine their exact functions.

Although it is not clear whether FA or MF are prohormones, hormones, or simply side products of JH biosynthesis in insects, the esterification of JH acids in the accessory glands of male *H. cecropia* (Shirk *et al.*, 1983) and the imaginal discs of *M. sexta* (Sparagana *et al.*, 1985) certainly suggests that FA can be converted to MF, and MF esterified to JH III, in tissues outside the CA. Research is needed on the existence, location, and activity of the enzymes *O*-methyl transferase and MF epoxidase to elucidate whether FA and MF are prohormones or hormones in their own right.

3.7.6.3. Evolutionary Inferences

FA is released from the nymphal CA of the cockroach, *D. punctata*, while homo/dihomo MF and FA appear to be products of the CA of adult female and male *P. unipuncta* (Cusson *et al.*, 1991a). It has recently been shown that in addition to JH III, the embryonic CA of *D. punctata* produce MF, with a shift to predominantly JH production as development proceeds (Stay *et al.*, 2002) (see Section 3.7.10.2). This evidence has led Stay *et al.* (2002) to postulate that the production of MF by the early embryonic CA is an ancient trait in Arthropoda, and that the original metamorphic and reproductive hormone in this more basal order was MF rather than JH. In light of the proposal that the ancestral role of JH was involved in embryogenesis (Truman and Riddiford, 1999), MF may have fulfilled this role in the early evolution of the Arthropoda, with a shift to JH III production as metamorphosis in the Insecta evolved.

Sehnal *et al.* (1996) have suggested that the postembryonic development in the ancestors of ametabolous insects occurred in the absence of JH and that the original function of JH in postembryonic life was the regulation of reproduction. As the occurrence of metamorphic molts evolved in ancient

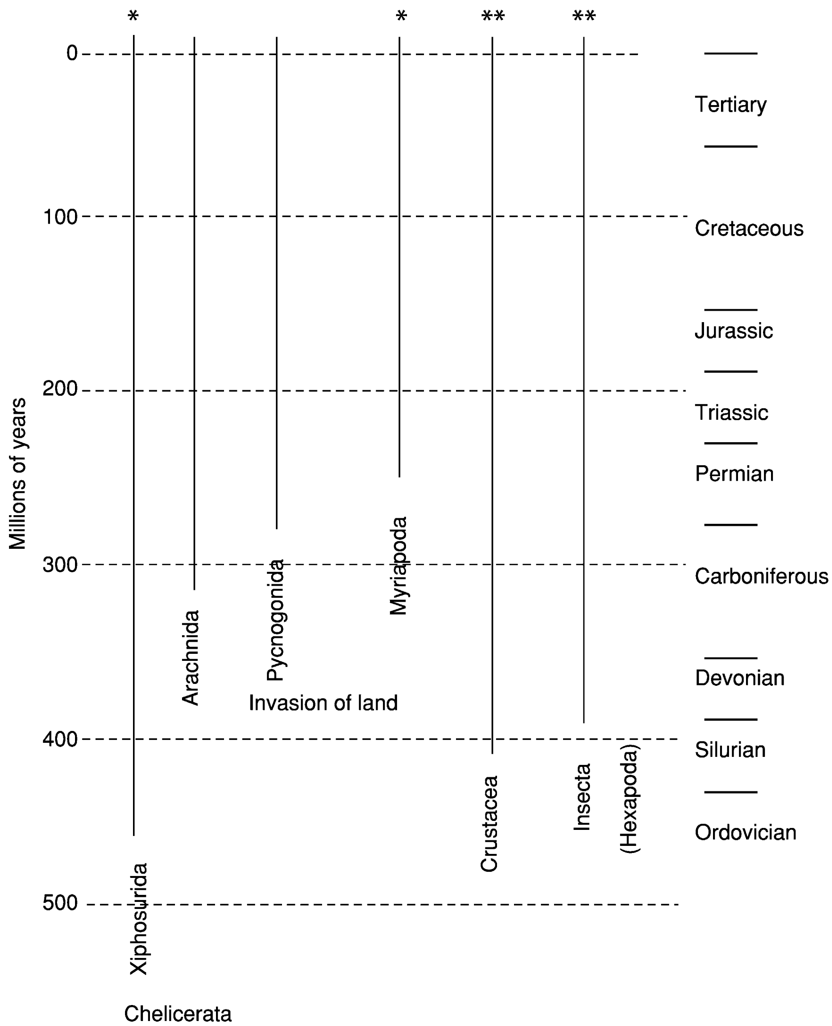

Figure 8 Evolutionary timeline of the appearance of the extant classes of Arthropoda. Classes in which JH effects have been demonstrated are noted with an asterisk (*). Classes in which JH or JH-like molecules have been identified are noted with a double asterisk (**).

arthropods, it is possible that a hormone (JH) that functioned in the embryo and the mature adult, but played no role in postembryological development, was coopted to regulate development before and after these metamorphic molts (Tobe and Bendena, 1999). In some insect species, JH appears to regulate the types of responses that would facilitate evolution of a larval stage, such as premature differentiation of the embryo and alterations in morphology (Truman and Riddiford, 1999). As outlined below (see Section 3.7.10.7), Truman and Riddiford (1999, 2002) have proposed that an advancement in the time of appearance of JH during embryogenesis may have been key to the evolutionary transformation of a pronymphal stage to the larval stage of holometabolous insects.

The production of more complex forms of JH may have occurred with the evolution of holometabolous development. At the present time, JH III is the only known form of JH in most insect species, particularly the Hemimetabola. With the exception of the HJHs (see Section 3.7.2.2), the more complex forms of JH, JH 0, iso-JH 0, JH I, methyl-JH I, JH III, and JHB_3, appear to occur only in two highly derived orders of holometabolous insect, the Lepidoptera and the Diptera. Furthermore, only Diptera appear to have evolved the ability to produce JHB_3. The production of the higher homologs and their multiple occurrence in some species appears to be related to the evolutionary development of intricate physiological events and their regulation. The exact physiological or developmental role of the different JHs or JH-like molecules in each class and order needs to be determined to further elucidate the role of JH in arthropod and insect evolution and by extension, the evolution of these molecules themselves.

3.7.7. Regulation of Juvenile Hormone Biosynthesis

A great deal of progress has been made since 1985 in understanding the regulation of JH biosynthesis by neurohormones, neuromodulators, and neurotransmitters (Feyereisen, 1985). At that time it was generally believed, based on a considerable body of *in vivo* studies, that physiological factors, mainly from the central nervous system, either stimulated (allatotropins) or inhibited (allatostatins) JH synthesis by the CA. Their chemical nature was unknown, but their existence was accepted, based on distinct and predictable changes in the hemolymph JH titer that related directly to physiological events, such as ecdysis of the larva and reproduction in the adult. By 1985, methods for maintenance of the CA *in vitro* had been established for a number of species, and two approaches to the measurement of JH biosynthesized *in vitro* had been developed: the radiochemical assay (Pratt and Tobe, 1974) (see Section 3.7.5.4) and the radioimmunoassay (Baehr *et al.*, 1976, 1979; Strambi, 1981) (see Section 3.7.5.3). Using these methods, the JH homologs synthesized by the CA *in vitro* have been found to be the same as those in hemolymph, although the homolog ratio may vary for CA that synthesize more than one JH. Moreover, developmental changes in JH biosynthetic activity by the CA *in vitro* parallel changes in the hemolymph JH titers (Feyereisen, 1985; Tobe and Stay, 1985). What factors elicit these changes in JH biosynthetic activity?

3.7.7.1. Neuropeptides

3.7.7.1.1. Allatotropins The first peptide to be isolated that affected JH synthesis *in vitro* was the allatotropin (AT) of *M. sexta* (Manse-AT) (Kataoka *et al.*, 1989). While this amidated tridecapeptide did not stimulate JH biosynthesis by larval or pupal CA *in vitro*, it did stimulate synthesis by adult CA at a concentration of 10^{-9} M. The gene for Manse-AT was isolated a decade later and was found to express three different mRNAs that differ from one another by alternative splicing (GenBank Accession no. U62100, U62101, U62102) (Taylor *et al.*, 1996). It has been suggested that the different mRNAs encode three distinct prohormones. Immunocytochemistry with polyclonal antibodies to Manse-AT and *in situ* hybridization with riboprobes for its mRNAs were used to show that Manse-AT exists in the central nervous system of *M. sexta* larvae. The former study found immunoreactivity in cerebral neurosecretory cells as well as axons in the corpora cardiaca (CC) and CA (Žitňan *et al.*, 1995), while the latter found only low levels in nonneurosecretory cells of the larval brain and subesophageal ganglion (Bhatt and Horodyski, 1999). Although Manse-AT stimulates the adult CA in this species, its mRNAs were not detected in prepupal, pharate pupal, or adult brains (Bhatt and Horodyski, 1999).

Is Manse-AT a functional AT in other lepidopteran species? There is direct evidence from several different studies that this is indeed the case. Manse-AT may be the true allatotropin in *P. unipuncta*: it has been cloned in this species (GenBank Accession no. AF212926) and Manse-AT immunoreactivity has been found in the CA (Truesdell *et al.*, 2000). Manse-AT has also been cloned from the silkworm *B. mori* (Park *et al.*, 2002) and has been purified from methanolic brain extracts of the fall armyworm, *Spodoptera frugiperda*, in which it stimulates adult CA (Oeh *et al.*, 2000, 2001). A cDNA encoding 134 amino acids, including an allatotropic peptide, has recently been cloned in this species (GenBank Accession no. AJ488181, AJ508061) (Abdel-Latief *et al.*, 2003), and the mature peptide is identical to Manse-AT. The *Spodoptera* peptide precursor has 84%, 93%, and 83% amino acid sequence identity with those of *M. sexta*, *P. unipuncta*, and *B. mori*, respectively. Manse-AT also stimulates JH synthesis by both larval and adult CA of *L. oleracea* (Audsley *et al.*, 1999a, 1999b, 2000), and the adult CA of another moth, *Heliothis virescens* (Kataoka *et al.*, 1989; Teal, 2002).

Manse-AT may be a functional AT in other orders as well. Immunological analyses indicate it is present in the abdominal nervous system of the cockroach *Periplaneta americana* (Rudwall *et al.*, 2000) and in the brain of the fly *P. regina* (Tu *et al.*, 2001). Moreover, it stimulates JH synthesis by the larval CA of the honeybee, *Apis mellifera* (Rachinsky and Feldlaufer, 2000; Rachinsky *et al.*, 2000), and the adult female CA of *P. regina* (Tu *et al.*, 2002).

3.7.7.1.2. Other roles for Manse-AT Since Manse-AT does not affect larval *M. sexta* CA, could it have another function in the larva? Indeed, Manse-AT has been shown to be a multifunctional molecule in *M. sexta*, as well as in other species. It exerts an apparently species-specific inhibition of ion transport in the midgut of *M. sexta* fifth instars (Lee *et al.*, 1998) and accelerates the heart rate in pharate adults, but not larvae (Veenstra *et al.*, 1994). It stimulates foregut contractions in the moths *Helicoverpa armigera* and *L. oleracea* (Duve *et al.*, 1999, 2000); acts as a cardioaccelerator in *Leucophaea maderae*, *P. americana* (Rudwall *et al.*, 2000),

and *P. unipuncta* (Koladich *et al.*, 2002); and is involved in the photic entrainment of the circadian clock of *L. maderae* (Petri *et al.*, 2002). Thus, a phenomenon observed with a number of other insect neuropeptides is illustrated by Manse-AT: it has multiple functions and these functions are stage-, tissue-, and species-specific.

3.7.7.1.3. Molecular biology of the allatotropins Horodyski and his colleagues have undertaken a detailed study of the molecular biology of the ATs. They have found that while levels of Manse-AT mRNAs are low or nonexistent in the brain, the Manse-AT gene is expressed in a variety of cells in other regions of the central nervous system and frontal ganglion in larval, pupal, and adult stages of *M. sexta* and that the cellular expression pattern in the nerve cord, as indicated by levels of Manse-AT mRNA, changes during metamorphosis (Bhatt and Horodyski, 1999).

Manse-AT-like peptides can be derived from each of three distinct precursor proteins that are the predicted products of alternatively spliced mRNAs (Taylor *et al.*, 1996). The basis for differences in the spliced mRNAs is the inclusion of one or two exons at the same location within the open reading frame. These exons contain a sequence that codes for a peptide with limited structural identity to Manse-AT (Horodyski *et al.*, 2001; Lee and Horodyski, 2002). The three expressed peptides have overlapping but nonidentical activities in JH biosynthesis assays with adult CA *in vitro* and in the inhibition of active ion transport across larval posterior midgut epithelium *in vitro*. The presence of the mRNA isoforms resulting from the alternative splicing is regulated in a tissue-and developmentally specific manner, suggesting changing roles for the resulting peptides at different life stages (Lee *et al.*, 2002). Finally, the expression of one of these mRNA isoforms is increased in the ventral nerve cord of *M. sexta* last instars subjected to treatments that normally reduce feeding and increase levels of JH in the larva: starvation, parasitization, or ingestion of the ecdysteroid agonist RH5992 (K.Y. Lee and Horodyski, 2002). These discoveries are the first to identify the pathway by which these treatments first have their effect. Whether this effect involves downstream regulation of the endocrine system, midgut ion transport, or another target is yet unknown.

3.7.7.1.4. Other allatotropins Until recently, Manse-AT was the only AT identified. However, an allatotropic immunoreactive peptide has been isolated from the abdominal ganglia of the mosquito *A. aegypti* (Veenstra and Costes, 1999) and found to have a unique sequence. It has now been shown that Aedae-AT has a stimulatory effect on adult female *A. aegypti* CA *in vitro*, with maximum stimulation at dosages of 10^{-8}–10^{-9} M, suggesting that this moiety is the true AT in *A. aegypti* (Li *et al.*, 2003). Furthermore, while neither the JH precursor FA nor Aedae-AT stimulates JH III synthesis by the CA of newly emerged females, when both are added to the incubation medium, high levels of JH III production occur, indicating that Aedae-AT makes the CA competent to make JH III from FA.

There are a number of studies that suggest the existence of at least seven other allatotropins (Stay, 2000; Li *et al.*, 2003). In the wax moth, *Galleria mellonella*, a protein fraction of larval brains was found to stimulate JH II synthesis by CA *in vitro*, and monoclonal antibodies raised to that fraction were used to identify a 20 kDa peptide by immunoblotting (Bogus and Scheller, 1996). Two pairs of immunoreactive neurosecretory cells in the *G. mellonella* brain and in the CC were identified with these monoclonal antibodies. One of the pairs of cerebral neurosecretory cells was immunoreactive with antibodies to Manse-AT as well, but because of the size of the putative Galme-AT, it is unlikely to be a homolog of Manse-AT. The investigators suggest that Manse-AT and Galme-AT have common epitopes due to splicing from the same preprohormone. Recent attempts to isolate the gene for this AT using an expression library and monoclonal antibodies have not been successful (Sehnal, personal communication).

A putative AT has been extracted from the subesophageal ganglion of the cricket *Gryllus bimaculatus*, and stimulates the adult CA of not only *Gryllus*, but also of another cricket, *Acheta domesticus* (Lorenz and Hoffmann, 1995). Extracts of the brain–subesophageal ganglion–CC–CA from the true bug, *Pyrrhocoris apterus*, stimulate JH biosynthesis by the CA of adults raised under long-day photoperiodic conditions (Hodkova *et al.*, 1996), and methanolic extracts of brain or CC from adult vitellogenic females of the locust *L. migratoria* stimulate JH III release from the CA of vitellogenic females 20–40-fold (Gadot *et al.*, 1987). These extracts also stimulate JH production by the CA of adult male *Locusta*, but not without some manipulation, since the CA must be chilled at 4 °C for 24 h to obtain the stimulatory response (Lehmberg *et al.*, 1992). Surgical manipulations and immunological studies suggest that the brain is the source of this factor (Couillaud *et al.*, 1984; Ulrich, 1985). Allatotropic activity was also extracted from the subesophageal ganglion and CC of adult male *M. loreyi*, and found to stimulate JH III acid and iso-JH II

synthesis by male CA *in vitro* approximately twofold (Kou and Chen, 2000).

3.7.7.1.5. Nonneural allatotropins The lack of effect of Manse-AT and other putative ATs on CA when one would assume an active stimulation of JH biosynthesis implies that there exist ATs of different structures than those isolated to date from neural tissue. Studies suggesting the existence of allatotropic molecules from nonneural sources represent the most intriguing line of research on the control of JH biosynthesis. There currently appear to be two sources for such factors: the ovary and the male accessory sex gland. Ovarian factors that effect JH production have been found in two species, the cockroach *D. punctata* and the cricket *G. bimaculatus*. In *D. punctata*, ovaries stimulate increased JH production in a stage-specific manner: ovaries just prior to ovulation are stimulatory while ovaries of pregnant females are not (Rankin and Stay, 1985). Stimulation is directly related to the size of the basal oocytes; ovaries with basal oocytes smaller than 0.8 mm or larger than 1.5 mm were not stimulatory. More recently, it has been demonstrated that *Diploptera* ovaries, fat body, and muscle can all stimulate JH synthesis by CA *in vitro* (Unnithan *et al*., 1998). Stimulation by the ovary is dose-dependent and sensitive, although the moiety responsible does not appear to be a peptide. In this species, however, the overall control of JH biosynthesis is very much dictated by allatostatins (see Section 3.7.7.2). In *G. bimaculatus* (Hoffmann *et al*., 1996), an increase in JH biosynthesis follows the implantation of ovaries into adult males. Whether this effect is mediated by a true AT is not clear, since an extract of ovaries did not stimulate JH synthesis *in vitro*.

A 36 amino acid peptide of known sequence from the male accessory sex gland of *D. melanogaster* (Chen *et al*., 1988; Schmidt *et al*., 1993) stimulates JH synthesis when transferred to the female during mating and also increases JH synthesis *in vitro* by the CA of adult female *D. melanogaster* (Moshitzky *et al*., 1996). The peptide has the same effect *in vitro* on CA from adult females of the moth *H. armigera* (Fan *et al*., 1999). By contrast, fragments of the C-terminal and a truncated N-terminal peptide from this *Drosophila* sex peptide (SP) inhibit JH synthesis *in vitro* by CA from both species. Since two N-terminal peptides stimulate JH synthesis, similar to the full-length molecule, it appears that the first five N-terminal amino acid residues are essential for CA stimulation by SP in both species (Fan *et al*., 2000). Moshitzky *et al*. (2003) recently reported that the *Drosophila* SP downregulates JH III bisepoxide synthesis *in vitro* by CA of another dipteran, the medfly *Ceratitis capitata*.

3.7.7.1.6. Future directions of research on allatotropins As proposed by Gilbert *et al*. (2000), the future directions of research on ATs should concentrate in several areas: (1) the identification of ATs in other orders and the sequences of the Manse-AT-like molecules in those lepidopteran species where Manse-AT has an effect; (2) the exploration of other functions for identified ATs; (3) the elucidation of the interaction of ATs and allatostatins in the overall control of JH biosynthesis; and (4) studies of their receptors and ligand–receptor interactions leading to downstream events that modulate synthesis. To this list should be added research on nonneural ATs.

3.7.7.2. Allatostatins

Allatostatins (ASTs), compounds that inhibit JH biosynthesis by the CA, can be grouped into three families. More than 170 different peptides belong to the largest of the families, the FGLamide ASTs, or the AST-A group. This family is characterized by the presence of a highly conserved pentapeptide in the C-terminus, Y/F-X-F-G-L-amide but displays considerable variability in length and sequence in their N-termini (Tobe and Stay, 2004). These ASTs, first identified by Stay *et al*. (1991a) in *D. punctata*, have now been found in many different insect species (Gade *et al*., 1997; Stay, 2000; Li and Noriega, personal communication). They have also been found in groups outside the insects, including Crustacea (Dircksen *et al*., 1999; Skiebe, 1999; Duve *et al*., 2002) and freshwater pulmonate snails (Rudolph and Stay, 1997). In *D. punctata* alone, there are 14 FGLamide ASTs, with one terminating in an isoleucine (Stay, 2000; Tobe and Stay, 2004). Although Lepidoptera have their own family of ASTs, an FGLamide AST was isolated and identified from *M. sexta* (Davis *et al*., 1997). FGLamide immunoreactivity is found in the brain, abdominal ganglia, neurohemal organs, and thoracic motor neurons of *M. sexta* larvae, but the processes of immunoreactive neurons in the CA are sparse. The authors concluded that in this species, the FGLamides are probably neuromodulatory, myomodulatory, and myotrophic.

The second family of ASTs, or AST-B group, has been identified in crickets, locusts, and stick insects and contains a common amino acid sequence of W_2W_9amide, that is, tryptophan residues at the 2 and 9 positions of the N-terminus (Lorenz *et al*., 1999, 2000; Tobe and Stay, 2004). Because these peptides in stick insects are variable in length, a

designation of W-X_6-Wamide has been assigned to this family (Tobe and Stay, 2004). At the present time there appear to be 17 of these peptides (Stay, personal communication): five in *G. bimaculatus*, six in *Carausius morosus*, with the remainder in orders as diverse as Lepidoptera (*M. sexta* and *B. mori*), Diptera (*D. melanogaster*), Orthoptera (*L. migratoria*), and Dictyoptera (*P. americana*) (Stay, 2000). A considerable number of these are not active in the species from which they were isolated, being identified solely on the basis of amino acid sequence.

The third family of ASTs, the AST-C group, has been identified in Lepidoptera and has been designated the PISCF family. The first to be discovered, an AST (Manse-AST) in *M. sexta*, was purified from pharate adult heads by Kramer *et al.* (1991) and shown to be a 15 residue, nonamidated peptide with a free C-terminus and with no homology to the cockroach ASTs. This neuropeptide is unique in another sense, in that it can completely inhibit JH production in *M. sexta*. Immunochemical and molecular techniques have shown that Manse-AST is present in other insects, including *P. unipuncta* (Jansons *et al.*, 1996), *L. oleracea* (Audsley *et al.*, 1998), *Spodoptera littoralis* (Audsley *et al.*, 1999a), and *D. melanogaster* (unpublished information cited in Stay, 2000). As with the other AST families, there is some question as to whether Manse-AST is the functional AST in all these species. Synthetic Manse-AST does not affect JH biosynthesis *in vitro* by *Drosophila* ring glands; in *P. unipuncta*, it does not inhibit larval CA or newly emerged adults, and inhibits adult female CA only 60% at a concentration of 10^{-6} M (Jansons *et al.*, 1996). Manse-AST inhibits JH synthesis *in vitro* by adult CA of *Heliothis* (*Helicoverpa) zea* (Kramer *et al.*, 1991) and *S. frugiperda* (Oeh *et al.*, 1999), but with the latter, only when the CA are first stimulated by Manse-AT. More recently, a synthetic Manse-AST was shown to inhibit JH II synthesis *in vitro* by CA from larval *L. oleracea* by approximately 70% (Audsley *et al.*, 2000). Manse-AST has also been demonstrated to modulate JH biosynthesis by the CA of insects of other orders, including *A. mellifera* (Rachinsky and Feldlaufer, 2000) and *P. regina* (Tu *et al.*, 2001). Thus, the PISCF ASTs do not appear to be limited to Lepidoptera, and may be the functional AST in other insect orders as well.

3.7.7.2.1. Effect of allatostatins on the juvenile hormone biosynthetic pathway Soon after the discovery of the ASTs, Pratt and his colleagues (Pratt *et al.*, 1989, 1991) showed that addition of exogenous farnesoate or mevalonate reverses the inhibition of JH biosynthesis *in vitro* by AST, suggesting that the action of this neuropeptide occurs before the synthesis of the isoprenoid and homoisoprenoid units that condense to form the JH backbone (Granger, 2003) (see Section 3.7.4.1). Tobe and his colleagues (Wang *et al.*, 1994) provided evidence that *D. punctata* allatostatin 4 (Dippu-AST 4) inhibits the activity of *O*-methyl transferase, the enzyme catalyzing the penultimate step in JH III biosynthesis in this species (see Section 3.7.4.1), but only at the moderately high concentration of 10^{-8} M. The authors concluded that this effect is probably secondary since Dippu-AST 4 inhibits JH synthesis at a much lower concentration and because a variety of precursors such as FA and (*E*,*E*)-farnesol were found in this and other studies to reverse the inhibition by Dippu-AST 4. Wang *et al.* (1994) concluded that Dippu-AST 4 is acting primarily on the earlier, rather than later, stages of JH biosynthesis. More recent work has confirmed that the most probable targets for the ASTs are the first committed steps in the synthesis of JH III, that is, either the transfer of citrate to the cytoplasm across the mitochondrial membrane or the cleavage of citrate to yield cytoplasmic acetyl CoA, a building-block for the isoprenoid and homoisoprenoid units (Sutherland and Feyereisen, 1996).

3.7.7.2.2. Locations of allatostatins in the insect AST-positive cerebral neurosecretory cells have been shown for all three families of ASTs by immunocytochemistry and *in situ* hybridization. Immunocytochemistry has demonstrated that these cells in *M. sexta*, *D. punctata*, and *G. bimaculatus* are usually located in the lateral protocerebrum, project to the CA on the contralateral side, and arborize in the CC and the CA (see Stay, 2000 for a summary). In some cases, medial neurosecretory cells are immunoreactive, as are some cells in the tritocerebrum, and these cells, together with some of the lateral cells, have been observed to arborize within the brain and thus can be considered interneurons (Stay *et al.*, 1992; Žitňan *et al.*, 1995). With the use of immunocytochemistry, ASTs have been demonstrated in other regions of the central nervous system including the peripheral nerves, the gut, the ovary, and the oviducts (Stay, 2000; Witek and Hoffmann, 2001; Garside *et al.*, 2002) (see Section 3.7.7.2.4). *In situ* hybridization has been used less frequently to locate ASTs within the insect, usually in combination with immunocytochemistry – for example, the identification of ASTs in hemocytes of *D. punctata* (Skinner *et al.*, 1997). The wide distribution of the ASTs indicated by these results reinforces their pleiotropic roles.

3.7.7.2.3. Pleiotropic roles of allatostatins It is clear from the enormous bulk of work on the ASTs that, as with the ATs, their actions are not limited to the modulation of the production of JH and that they frequently do not have an allatostatic role in the insect from which they are isolated. The functions of ASTs have been loosely grouped into six categories: (1) inhibition of JH biosynthesis; (2) modulation of muscle contraction in the heart and gut; (3) modulation of neural activity in the central nervous system; (4) inhibition of vitellogenin synthesis/release; (5) inhibition of the production of ecdysteroids by prothoracic glands and ovaries *in vitro*; and (6) modulation of digestive enzyme activity (Bellés *et al.*, 1999; Stay, 2000; Gade, 2002; Tobe and Stay, 2004). The same AST can exert several different tissue-specific effects at various developmental stages in different insect species.

The ubiquitous nature of these peptides in insects and in other invertebrates, plus the conservation of core sequences within them, speaks to their ancient origin. It has been suggested that their function as regulators of JH biosynthesis evolved before the rise of the insects (Tobe and Stay, 2004). The great profusion of ASTs, even within a single species, suggests flexibility and overlap in their functions, although it is clear that in some instances, a single AST or structurally similar group can have a narrowly defined function and only minimal activity in other roles. It has been noted that in insect species more recently evolved than cockroaches, there are fewer ASTs (13–14 in cockroaches compared to 5–9 in Diptera and Lepidoptera), and a concurrent loss of their role as inhibitors of JH biosynthesis (Tobe and Stay, 2004). Since a single AST can have different effects at different times, it is not possible to conclude that the loss of AST function is the direct result of the loss of their numbers, and studies of the molecular evolution of the ASTs are needed to resolve this question (Donly *et al.*, 1993a; Ding *et al.*, 1995; Bellés *et al.*, 1999).

3.7.7.2.4. Other types of allatostatins A partially identified factor from the brains of late last instars of *M. sexta* has been found to inhibit JH production irreversibly in a combination *in vivo/in vitro* assay (Bhaskaran *et al.*, 1990; Unni *et al.*, 1993). CA exposed *in vitro* to the brain factor are then implanted into penultimate instars to assay their activity. Because this factor appears to be responsible for stable inhibition of JH biosynthesis until after metamorphosis, it was given the name allatinhibin to distinguish it from ASTs, whose effect is fast and reversible.

There are also nonneural factors of unknown structure that can inhibit JH synthesis by the CA. The ovary appears to be a prime source for these factors, which is not surprising, given the fact that JH regulates reproduction. Early work by Stay and Rankin (Stay *et al.*, 1980; Rankin and Stay, 1985) indicated that the ovary of *D. punctata* has a role in the decrease of JH synthesis at the end of vitellogenesis. Allatostatic peptides have been extracted from prechorionogenic ovaries of *G. bimaculatus* (Hoffmann *et al.*, 1996) and *L. migratoria* (Ferenz and Aden, 1993). The partially purified *Locusta* ovarian factor is small (1–1.3 kDa) and inhibits JH synthesis *in vitro* in a dose-dependent manner. The ovarian extract from *G. bimaculatus* also inhibits JH synthesis by CA *in vitro* in a dose-dependent manner, with the potency of inhibition dependent on the stage of the animal from which the CA are taken. Immunoassays using separate polyclonal antisera to *Gryllus* ASTs A1 (FGLamide) and B1 (W-X_6-Wamide) have recently been employed to demonstrate AST-A-like and -B-like immunoreactivity in ovary extracts and partially purified HPLC fractions (Witek and Hoffmann, 2001). The immunoreactive fractions inhibit JH biosynthesis *in vitro*. The AST- and AST-B-epitopes are immunolocalized to the cortical cytoplasm of oocytes in ovaries of both larval and adult crickets; no neural structures within the oocytes are stained. In *D. punctata*, where the ovary has a clear role in the decrease of JH biosynthesis at the end of vitellogenesis, the ovarian factor responsible could be either a neuropeptide sequestered by the ovary or an ovarian peptide with an AST epitope. With the use of a competitive reverse transcriptase polymerase chain reaction assay (RT-PCR) to quantify AST expression, it has been demonstrated that both the lateral and common oviducts and ovaries express message for ASTs and that there are changes in the pattern of expression during the reproductive cycle (Garside *et al.*, 2002). Unlike the situation in *G. bimaculatus*, however, there are no immunoreactive cell bodies in the oviducts or ovary, but there is immunoreactivity in the terminal abdominal ganglion and ventral nerve 7, branches of which innervate the oviducts. Thus, the transcripts quantified by RT-PCR may be generated in the axonal compartment of the allatostatin-containing nerves innervating these structures.

3.7.7.2.5. Molecular biology of the allatostatins The first AST gene to be cloned was that from *D. punctata*, which encoded for a 41.5 kDa precursor polypeptide (GenBank Accession no. U00444) (Donly *et al.*, 1993a, 1993b). This polypeptide

contains the 13-member family of AST peptides that exist in this species, with appropriate processing sites for endoproteolytic cleavage and amidation. The ASTs are clustered in the precursor, and separating the clusters are three acidic spacers. These spacers are believed to stabilize the precursor, but they have also been proposed to code for a related peptide (Donly *et al.*, 1993a; Ding *et al.*, 1995). Southern blot analysis revealed that there is a single copy of the AST gene per haploid genome. The prepro-ASTs for all cockroach species examined are similar in size, the organization of the ASTs within them (13 or 14) is conserved, and the separation of groups of peptides by acidic domains is maintained (Ding *et al.*, 1995; Bellés *et al.*, 1999). The different AST sequences in the gene of one species were derived from duplication events. Thus, the AST-A family in cockroaches is a good example of a family of peptides with similar sequences derived from a single precursor encoded by a single gene.

The *Drosophila* Genome Project database was screened for sequences corresponding to various insect ASTs. The resulting alignments enabled the cloning of the cDNA for a prepro-*Drosophila* AST containing four putative A-type ASTs (GenBank Accession no. AF263923) (Lenz *et al.*, 2000). A similar approach was taken to identify a prepro-B-type AST that contains two B-type ASTs (GenBank Accession no. AF312379) (Williamson *et al.*, 2001a, 2001c), and a prepro-C-type AST that contains a single C-type AST with one amino acid residue difference from the *M. sexta* C-type AST. The sequence of the C-type AST is identical to that of previously identified dipteran ASTs (GenBank Accession no. AF316433) (Williamson *et al.*, 2001b).

The mRNA for the *G. bimaculatus* AST encodes a hormone precursor that contains at least 14 putative hormones (GenBank Accession no. AJ302036) (Meyering-Vos *et al.*, 2001). Five of these were previously identified in this species, while the remaining ones are known from other species. The deduced prepro-AST sequence is similar to that in cockroaches, but shorter than that of locusts. Regions of the acidic spacers that separate clusters of hormones are conserved between cockroaches and crickets, providing additional evidence that the spacers have a real function.

Identification of the prepro-AST message has been made in two other species. In the mosquito *A. aegypti* the message is about 3×10^3 bases in length and encodes five ASTs (GenBank Accession no. U66841) (Veenstra *et al.*, 1997). The prepro-AST genes are expressed in both abdominal ganglia and midgut. Three cDNAs of 1506 bases encode ASTs in the German cockroach, *Blattella germanica* (Yang *et al.*, 2000) and all have a nucleotide sequence with strong similarity (~80%) to that of other cockroach cDNAs for the prepro-AST.

3.7.7.2.6. Control of allatostatin titers The effect of ASTs on JH biosynthesis may occur in a paracrine fashion, i.e., local release within the CA from the axons of cerebral cells that produce these neuropeptides, or in a true endocrine fashion, via the hemolymph. By either means, receptors would mediate the effect of the neuropeptide (see Section 3.7.7.2.7) and it is ultimately the combination of titer and receptor that determines the effect of a neuropeptide. Recent work indicates that degradative mechanisms targeting ASTs can control the levels to which the CA are exposed. Initial work by Bendena *et al.* (1997) demonstrated that, like most neuropeptides, *Diploptera* ASTs are susceptible to rapid degradation. One of the ASTs of *B. germanica* has a half-life of 3–6 min in the intact insect, thus explaining why high doses are required for biological effects *in vivo* (Peralta *et al.*, 2000). A study of the degradation of Manse-AST by enzymes in foregut extracts of *L. oleracea* revealed a half-life of 5 min for the AST. Its degradation resulted in two products, both of which are cleaved at the C-terminal side of arginine residues (Audsley *et al.*, 2002).

Dippu-AST 7 and Dippu-AST 9 are subject to two primary catabolic cleavage steps: cleavage by a putative endopeptidase, yielding a C-terminal hexapeptide, and subsequent cleavage of this product by an aminopeptidase to yield a C-terminal pentapeptide. Neither of these hemolymph enzymes inactivates the ASTs, since the C-terminal pentapeptide contains the minimal sequence necessary for the inhibition of JH synthesis (Garside *et al.*, 1997a). However, there are membrane-bound enzymes in the brain, gut, and CA that cleave ASTs at the C-terminus, inactivating them in a two-step process (Garside *et al.*, 1997b). Pseudopeptide mimetic analogs of Dippu-ASTs have been synthesized that are resistant to degradation by hemolymph and tissue-bound peptidases, and these can significantly inhibit JH biosynthesis by CA when injected into mated *Diploptera* females, as measured by an *in vitro* assay using CA explanted from these females (Nachman *et al.*, 1999; Garside *et al.*, 2000). An outcome of this research is the creation of tools with which the actions of ASTs can be studied in detail, using degradation-resistant analogs.

3.7.7.2.7. Allatostatin receptors The type and number of receptors for ASTs in the CA control

the timing, duration, and potency these neuropeptides will have on JH biosynthesis. Work on AST receptors has also flourished, particularly with the discovery of such receptors in *D. melanogaster*, the model insect for genetic and molecular biological investigations. The first study to identify AST receptors was carried out by Cusson *et al.* (1991b), who used photoaffinity labeling to demonstrate two putative receptors in *Diploptera* CA. Subsequently, a single receptor for Dippu-AST 7 with a K_d of 7.2×10^{-10} M was found in the CA (Yu *et al.*, 1995), in addition to a single 37 kDa receptor in adult female brains that recognized both Dippu-AST 5 and Dippu-AST 7. Since a single K_d was obtained with AST 5 (9×10^{-10} M), but two with AST 7 (1.5×10^{-9} and 3.8×10^{-9} M), it was suggested that there were two receptor sites for Dippu-AST 7 in the brain. A subsequent structure–activity study using synthetic analogs of Dippu-AST 2 revealed two receptor types in *Diploptera* CA (Pratt *et al.*, 1997). The investigators proposed that the C-terminal portion of ASTs contains both the "message" determining its full effect, as well as "address information" determining its binding affinity for the receptor, and that divergent evolution of receptor types occurred with the evolution of multiple ASTs from a common ancestor. More recently, a radioligand-binding assay was used to identify a single class of binding sites for Dippu-AST 7 in midgut membranes with a K_d of 2.1×10^{-10} M (Bowser and Tobe, 2000). In competitive binding assays, Dippu-AST 7 and AST 2 exhibit a higher affinity for the midgut receptor than AST 5, 9, 10, or 11, while the other ASTs did not compete. Clearly, cloning and sequencing of these receptors is needed to sort out the ubiquitous occurrence and varied functions of the multiple ASTs.

Two laboratories have cloned G-protein coupled receptors (see **Chapter 5.5**) from *D. melanogaster* that are structurally related to mammalian somatostatin/galanin/opioid receptors (GenBank Accession no. AF163775: Birgul *et al.*, 1999; GenBank Accession no. AF253526: Lenz *et al.*, 2000), but which bind a peptide related to the AST family and thus appear to be AST receptors. Lenz *et al.* (2000) termed their receptor DAR-1. Screening the *Drosophila* genome database, these investigators found a second G-protein coupled receptor, termed DAR-2, with a 47% amino acid residue similarity with DAR-1 (Lenz *et al.*, 2001). Expression studies of DAR-2 in Chinese hamster ovary cells indicated it is the cognate receptor for four *Drosophila* A-type ASTs that bind to the receptor differentially. The DAR-2 gene is expressed in embryos, larvae, pupae, and adults, and is mainly expressed in the gut of third instars. Since the larval gut of *D. melanogaster* contains cells expressing the gene for the prepro-ASTs, the authors concluded that DAR-2 mediates AST-induced inhibition of gut motility. In a simultaneous study, both DAR-1 and DAR-2 were expressed in Chinese hamster ovary cells and tested for activation using synthetic *Drosophila* ASTs and selected *Diploptera* ASTs (Larsen *et al.*, 2001). Both types of ASTs activate DAR-1 and DAR-2, indicating ligand redundancy and cross-species activity.

An apparent A-type AST receptor has been cloned from the cockroach *P. americana*, with about 60% amino acid similarity in the transmembrane regions to the two identified *Drosophila* receptors. When functionally expressed in *Xenopus* oocytes, this receptor exhibits high affinity for cockroach ASTs (GenBank Accession no. AF336364) (Auerswald *et al.*, 2001). An A-type AST receptor has also been cloned from the silkworm *B. mori* (GenBank Accession no. AH011256) (Secher *et al.*, 2001). This receptor (BAR) shows 60% amino acid residue identity with DAR-1 and 48% with DAR-2. The genomic structure of BAR displays two introns that are coincident with, and have the same intron phasing as, two introns in DAR-1 and DAR-2, and the authors conclude that these three receptors are both structurally and genomically related. BAR mRNA is expressed mainly in the gut, and thus this receptor appears to be a gut peptide hormone receptor. Further studies should focus on identifying AST receptors in the CA to define the second messenger cascade that translates the AST signal in the gland, and to elucidate the evolutionary path by which this large class of peptides evolved to regulate JH biosynthesis.

3.7.7.2.8. Corpora allata sensitivity to allatostatins Humoral factors may play a role in regulating the sensitivity of the CA to ASTs. Unnithan and Feyereisen (1995) found that acquisition of sensitivity to AST by CA from adult mated *Diploptera* females occurs just before choriogenesis and is dependent on a humoral factor. The investigators could manipulate sensitivity by various experimental techniques, e.g., ovariectomy of vitellogenic females disrupts both JH biosynthesis and acquisition of sensitivity. This line of research deserves more investigation, since it could represent the upregulation of AST receptors by other circulating hormones.

3.7.7.3. Other Factors Regulating Juvenile Hormone Biosynthesis

3.7.7.3.1. Neurotransmitters It has long been thought that regulation of JH biosynthesis is exerted

via the axons of cerebral neurons that innervate the CA. Yet, it is clear from research on the ASTs that this control could occur via the hemolymph, with release from the CC, the neurohemal organ for cerebral neuropeptides, or other sites of AST-producing cells. Control of JH synthesis by neurotransmitters is also likely, since some of the nerve cells innervating the CA are ordinary neurons (Sedlak, 1985).

Octopamine, a primary insect neurotransmitter, was the first neurotransmitter to be identified in the CA of locusts and cockroaches (Evans, 1985). Studies of octopamine effects on JH biosynthesis *in vitro* have shown either stimulation or inhibition, depending on the species. Octopamine stimulates JH biosynthesis in adult *L. migratoria* (Lafon-Cazal and Baehr, 1988) and in larvae (Rachinsky, 1994) and adults (Kaatz *et al.*, 1994) of *A. mellifera*, but inhibits synthesis in adults of the cockroach *D. punctata* (Thompson *et al.*, 1990) and the cricket *G. bimaculatus* (Woodring and Hoffmann, 1994). In *D. punctata*, inhibition by octopamine is bimodal, with peaks occurring at 10^{-10} M and 10^{-4} M (Thompson *et al.*, 1990).

Recent work on adult females of *D. punctata* has provided the first indication that JH biosynthesis by the insect CA may be affected by the fast excitatory neurotransmitter L-glutamate, acting via ionotropic receptors to modulate the intracellular Ca^{2+} concentration (Pszczolkowski *et al.*, 1999) (see Section 3.7.7.4.3). Since high Mg^{2+} and kynurenate treatments inhibit the L-glutamate-induced stimulation of JH biosynthesis, it was proposed the NMDA (magnesium-sensitive) and non-NMDA (kynurenate-sensitive) receptors are present in the *Diploptera* CA and are involved in the regulation of JH synthesis. A subsequent study, monitoring rates of JH biosynthesis by *Diploptera* CA *in vitro* in response to L-glutamate agonists and antagonists, identified the receptors present as NMDA-, kainate-, and/or quisqualate-sensitive subtypes of ionotropic receptors. These receptors are coupled to calcium ion channels and are thus ionotropic channels rather than metabotropic channels, the latter being coupled to inositol (IP3)-stimulated Ca^{2+} release (Chiang *et al.*, 2002a).

The first suggestion that dopamine might be involved in the regulation of JH production was found in a study of dopamine in the brains of two cockroach species, where its levels fluctuated significantly in relation to events during the JH regulated ovarian cycle (Owen and Foster, 1988; Pastor *et al.*, 1991a). A similar situation has recently been described in the fire ant, *Solenopsis invicta* (Boulay *et al.*, 2001). Shortly after the study by Pastor *et al.* (1991a), it was reported that dopamine affects JH synthesis *in vitro* by the CA of adult female *B. germanica*, and that its effect was either stimulatory or inhibitory, depending on the stage of the ovarian cycle (Pastor *et al.*, 1991b). A screen of neurotransmitters in the larval *Manduca* CA using electrochemical detection-HPLC revealed that dopamine was the only biogenic amine in the gland (Granger *et al.*, 1996). Immunocytochemical analysis further corroborated these studies and demonstrated that dopamine is present in both the brain and CA (Granger, unpublished data). Dopamine affects JH synthesis by larval *Manduca* CA *in vitro* differentially, stimulating both JH synthesis and cAMP production by CA in very early fifth stadium glands but inhibiting production of both JH and cAMP after day 2 (Granger *et. al.*, 1996) (**Figure 9**).

Another line of evidence implicating dopamine in the regulation of larval development, possibly through an effect on the CA, derives from studies of the effects of parasitism of the armyworm *Pseudaletia separata* by the wasp *Cotesia kariyai*. Parasitism by this species elevates dopamine levels in the nerve cord and hemolymph, slows normal development, and delays pupation of the host (Noguchi *et al.*, 1995; Noguchi and Hayakawa, 1996). Dopamine levels are significantly elevated in the hemolymph of *M. sexta* larvae parasitized by the wasp *Cotesia congregata* (Hopkins *et al.*, 1998), although no developmental effects are related to the increase. Significantly higher levels of dopamine have also been found in the hemolymph and central nervous system of diapause-bound pupae of the armyworm *Mamestra brassicae* (Noguchi and Hayakawa, 1997) (see **Chapter 3.12**). The relationship of elevated dopamine levels and delayed pupation is unclear, although persistent levels of JH are known to delay pupation in Lepidoptera. It is tempting to think that elevated levels of dopamine are stimulating CA activity. However, the converse could equally be true: persistent JH synthesis delaying pupation could elevate dopamine levels. A similar situation occurs in the honeybee: JH has been implicated in the control of honeybee division of labor, where elevated levels of octopamine and serotonin in the antennal lobes of adult workers are associated with foraging behavior (Schulz and Robinson, 2001) (see **Chapter 3.13**). Treatment of honeybees with methoprene elevates octopamine levels, and these authors concluded that JH modulates octopamine levels in the honeybee brain, and that octopamine acts downstream of JH to influence behavior (Schulz *et al.*, 2002).

Neurotransmitter receptors exist in the CA, which is not surprising given that these glands

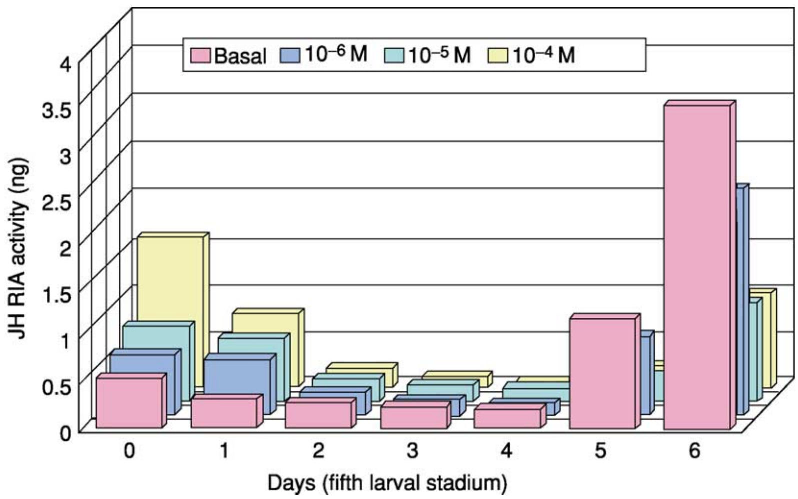

Figure 9 Effect of dopamine synthesis on JH biosynthesis in *vitro. Manduca sexta* CA from different days during the last larval stadium were incubated with increasing concentrations of dopamine. JH III/JH III acid synthesis was measured by radioimmunoassay (RIA) and expressed as ng of JH III radioimmunoassay equivalents. (Adapted from Granger, N.A., Sturgis, S.L., Ebersohl, R., Geng, C.X., Sparks, T.C., **1996**. Dopaminergic control of corpora allata activity in the larval tobacco hornworm, *Manduca sexta. Arch. Insect Biochem. Physiol. 32*, 449–466.)

are extensively innervated by the axons of cerebral neurons and neurosecretory cells. The receptors for biogenic amines belong to a large superfamily of G-protein coupled receptors, and the nucleotide sequences of the octopamine, tyramine, dopamine D1 and serotonin receptors are known for *D. melanogaster, A. mellifera, H. virescens, B. mori*, and *L. migratoria* (von Nickisch-Rosenegk *et al*., 1996; Blenau and Baumann, 2001). Binding of dopamine to D1 receptors increases adenylyl cyclase activity, while binding to D2 receptors either has no effect or inhibits adenylyl cyclase (Gingrich and Caron, 1993; Vernier *et al*., 1995; Huang *et al*., 2001). D2-like receptors have not yet been cloned in any insect, although pharmacological studies suggest they exist (Blenau and Baumann, 2001), and receptors for biogenic amines in the CA have not been pharmacologically characterized except for the dopamine receptors in the CA of *M. sexta* last instars (Granger *et al*., 2000). Because dopamine both stimulates and inhibits JH synthesis and adenylyl cylase activity, depending on developmental stage, these glands undoubtedly possess both D1-like and D2-like receptors (Granger *et al*., 1996). The CA D2-like receptor was found to have some pharmacological resemblance to vertebrate D2 receptors, but certain vertebrate D1 receptor agonists/antagonists were found to be equally effective as D2 receptor agonists/antagonists. By contrast, the CA D1-like receptor was found to be pharmacologically distinct from vertebrate D1 receptors (Granger *et al*., 2000). This fits with the overall picture of dopamine receptors that have been cloned from insects–they display pharmacological properties that set them apart from vertebrate receptors (Blenau and Baumann, 2001).

3.7.7.3.2. Interendocrine control by ecdysteroids If, according to the axiom of Carroll Williams (1976), JH is the handmaiden of ecdysone, then one might ask: Do ecdysteroids regulate JH biosynthesis? The evidence that ecdysteroids may regulate CA activity comes primarily from Granger, Bollenbacher, and their colleagues, who determined that regulation is interendocrine and occurs via the brain. The increase in the ecdysteroid titer, specifically 20-hydroxyecdysone (20E), that elicits pupal commitment in the last stadium of *M. sexta* and other Lepidoptera, also stimulates the synthesis of JH acids by *Manduca* CA. This effect, exerted only when the CA are incubated as a complex with the brain–CC, occurs in response to physiological concentrations of 20E, and results in the postcommitment increase in the hemolymph titers of JH acids that have been shown to be necessary for development to the pupa (Whisenton *et al*., 1985; Watson *et al*., 1986; Granger *et al*., 1987). A subsequent investigation of the kinetics of the 20E effect revealed that maximum stimulation was achieved in 1 h, supporting the idea of an indirect effect, probably via the brain, and suggesting the existence of a mediating factor (Whisenton *et al*., 1987). Physiological concentrations of 20E were also shown to stimulate JH synthesis in *Manduca* fourth stadium CA, taken before the normal rise in CA activity at the end of the stadium. This suggests that interendocrine control of JH biosynthesis during larval molting is also exerted by 20E (Whisenton *et al*., 1987), and that this effect

is specific for a biologically active ecdysteroid, since two biologically inactive ecdysteroids, 22-isoecdysone and 5-α-ecdysone, failed to stimulate the CA. The effective concentrations that stimulate the CA differ by about 200-fold, $\sim 1\,\mu g\,ml^{-1}$ during larval development and $0.02\,\mu g\,ml^{-1}$ during pupal commitment, in keeping with the hemolymph concentrations of 20E at those times (Bollenbacher *et al.*, 1981). Interestingly, both of these concentrations stimulate CA from last instars at the time of commitment, and there are no other maxima between these two concentrations (**Figure 10**) (Granger, unpublished data). Given the fact that Manse-AT does not affect *Manduca* larval CA, it would appear that 20E acts in lieu of an AT in larvae.

Incubation of brain–CC–CA complexes from pharate *Manduca* pupae with physiological concentrations of 20E resulted in a 40% decrease in the production of JH acids (Granger *et al.*, 1987). This decrease did not occur if the glands were incubated with, but separated from, the brain–CC complex. While the level of inhibition seen in these experiments is not sufficient to account for the inactivation of the CA by the end of the stadium, this mechanism could act in concert with Manse-AST, which does inhibit larval glands.

Granger *et al.* (1996) have demonstrated that the dopamine stimulation of JH synthesis by CA from day 0 last instars of *M. sexta* may be downregulated by 20E. Ecdysteroid receptors (see **Chapter 3.5**) have been detected in the nuclei of *Manduca* CA as early as day 3 of the last stadium (Bidmon *et al.*, 1992), suggesting the possibility that the negative effect of ecdysteroids on JH biosynthesis involves nuclear receptors and transcriptional control. In a study of the ecdysteroid receptors in *Manduca* CA, it was found that both components of the heterodimeric receptor complex – ecdysteroid receptor (ECR) and Ultraspiracle protein (USP) – are expressed (Gilbert *et al.*, 2000; Granger and Rybczcynski, unpublished data). The CA contain two or more USP isoforms that are probably the phosphorylation states of two primary translation products. Preliminary results show that the p49 USP isoform in the CA increases during the feeding period and after commitment to pupation in the last larval stadium (**Figure 11**). The larger USP isoforms show a maxima surrounding the time of the commitment peak in ecdysteroid titer and during the premolt ecdysteroid peak. This pattern directly contrasts with that of the ECRs which show few differences in relative abundance or isoform diversity in this stadium (Gilbert *et al.*, 2000). Culture *in vitro* of day 1 CA with ecdysteroids causes a decrease in the predominance of the larger USP isoforms and an increase in p49 (**Figure 11**). This response is also seen in prothoracic glands (Song and Gilbert, 1998). It may be that the changes in ecdysteroid titer are responsible for changes in USP isoform number and abundance during the last stadium and thus might modulate the number and/or kind of genes (for dopamine receptors, for example, which are affected by the ecdysteroid titer) activated by a given concentration of ecdysteroid receptor.

With regard to other possible molecular interactions of ecdysteroids and the JH biosynthetic pathway, the evidence is largely conjectural. As discussed above (see Section 3.7.4.2), a mammalian farnesoid receptor, FXR, is affected by JH, methoprene, and farnesol in a mammalian transactivation assay. Weinberger (1996) has demonstrated that bile acids, 3-α-hydroxysteroids, and oxysterols are endogenous FXR affectors. Is it possible that another class of steroids, the ecdysteroids, also affect FXR, and could this be a mechanism by which ecdysteroids affect JH biosynthesis?

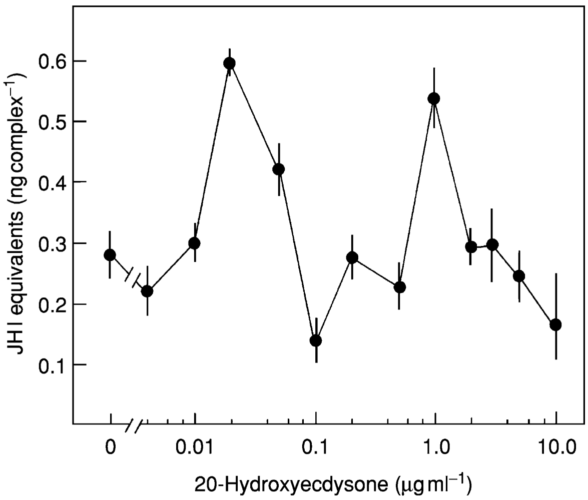

Figure 10 Effect of increasing concentrations of 20-hydroxyecdysone on JH I acid biosynthesis *in vitro* by CA incubated as a brain–CC–CA complex, from gate II, day 3 fifth instars of *M. sexta*. Each datum point represents the mean (±) SEM, where $n = 5$–6 incubations. Results are expressed as ng JH I RIA equivalents synthesized per complex in a 6 h incubation. (From Granger, unpublished data.)

3.7.7.3.3. Regulation of juvenile hormone biosynthesis by juvenile hormone

There is a paucity of direct evidence that JH regulates its own synthesis. An early study by Granger *et al.* (1986) indicated that neither exogenous JH I nor JH III can inhibit JH I acid biosynthesis by CA from last instars of *M. sexta*. A later, more detailed study of JH feedback in this system confirmed this result (Granger, unpublished data). Richard and Gilbert (1991), using *Drosophila* ring glands, demonstrated that

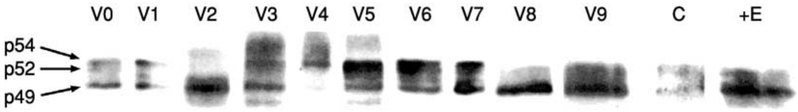

Figure 11 Ultraspiracle expression in the corpus allatum during the fifth larval stadium of *M. sexta*. The proportion of the p49 isoform increases as the stadium progresses, and this shift can be replicated *in vitro* by incubating CA with 20-hydroxyecdysone as described by Song and Gilbert (1998). CA were dissected on the indicated days and subjected to sodium dodeylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) followed by immunoblotting with an anti-USP antibody (Song and Gilbert, 1998). V0–V9, days of the fifth larval stadium; C, control, V1 CA; E, V1 CA incubated with 10 μM 20E for 18 h. Arrows indicate isoforms of USP. (Rybczynski, Moshitzky, and Granger, unpublished data.)

JH III and JHB_3, but not MF, reversibly inhibited biosynthesis of JH III, JHB_3, and MF. These results are in agreement with the generally accepted mechanism of negative feedback regulation of an endocrine gland by its product(s) (see **Chapter 3.8**).

As discussed above (see Section 3.7.4.2), mammalian orphan nuclear receptors now appear to be involved in the coordination of the lipid-based metabolic signaling cascade (Chawla *et al*., 2001). One of these nuclear receptors, RXR, is affected by farnesol and JH, and thus might be of significance in considering regulatory feedback loops of JH on JH biosynthesis. Molecular approaches have led to spectacular advances in our understanding of insect endocrinology, and the future holds great promise with respect to the elucidation of interendocrine control mechanisms.

3.7.7.4. Second Messengers

Receptors for neuropeptides and neurotransmitters are usually coupled to intracellular reaction cascades, regulating the level of second messengers that transduce these signals (see **Chapter 3.2**). The influence of a variety of second messenger systems on JH biosynthesis has been investigated both independently and as signal transducers, including cyclic AMP (cAMP), cyclic GMP (cGMP), phospholipid/protein kinase C, inositol phosphates, diacyl glycerol (DAG), and calcium (Ca^{2+}).

3.7.7.4.1. Cyclic AMP The role of cAMP in the regulation of JH biosynthesis has been studied most extensively in the cockroach *D. punctata*. In an initial study, compounds that increased intracellular cAMP were found to inhibit JH synthesis *in vitro* (Meller *et al*., 1985). These data suggest that the effect of the ASTs is mediated by cAMP. Of various compounds tested, 8-bromo-cAMP, which is resistant to hydrolysis by phosphodiesterases, and forskolin, a diterpene that activates adenylyl cyclases, were both potent inhibitors of JH synthesis *in vitro*. Furthermore, developmental changes in CA sensitivity to forskolin were found to parallel those to ASTs (Stay *et al*., 1991a), and exposure of CA to crude brain extracts resulted in both an increase in cAMP and a decrease in JH production (Aucoin *et al*., 1987). However, a subsequent study by Tobe (1990) showed that cAMP levels were low in virgin female CA, whose JH biosynthesis is inhibited. More cGMP than cAMP was found in these CA, and cGMP was lowest when JH biosynthesis was at a maximum in mated females. Levels of cAMP and cGMP were then measured in the CA of both virgin and mated females exposed to synthetic Dippu-ASTs 1–4 (Cusson *et al*., 1992). No significant changes in the levels of either cyclic nucleotide were found, strongly suggesting that neither of these cyclic nucleotides is involved in the signal transduction of the ASTs. Octopamine inhibition of JH biosynthesis in this species is bimodal (see Section 3.7.7.3.1), but only the inhibition in response to the higher concentration of octopamine (10^{-4} M) results in a rise in the levels of intracellular cAMP (Thompson *et al*., 1990). Thus, the caveat expressed by Meller *et al*. (1985), that the effects of pharmacological agents might only mimic the cellular response to inhibitory factors, appears to hold in *D. punctata*, where only a moderately high dose of octopamine exerts an inhibitory effect via an octopamine-sensitive cAMP.

By contrast, cAMP has a stimulatory effect on larval CA activity in *M. sexta* and is involved in transduction of the dopamine signal. Granger *et al*. (1994) found that relatively inactive CA, such as those of day 4 of the last stadium or from the *black larval* (*bl*) mutant, were sensitive to a variety of compounds *in vitro* that elicited, or mimicked the effects of elevated intracellular cAMP levels. It was also discovered that the stage-specific effects of dopamine on JH/JH acid biosynthesis by *M. sexta* larval CA *in vitro* were mediated by a calcium/calmodulin sensitive adenylyl cyclase (Granger *et al*., 1995b). Dopamine at concentrations of 10^{-6} and 10^{-7} M stimulated adenylyl cyclase activity in homogenates of glands taken from day 0 last instars, when this neurotransmitter stimulates JH biosynthesis, but inhibited enzyme activity in homogenates of day 6 glands, when dopamine inhibits CA activity (Granger *et al*., 1995b, 1996). A similar approach demonstrated that octopamine had no effect on

enzyme activity in gland homogenates over a wide range of concentrations. It was subsequently found that effects of dopamine receptor agonists and antagonists on JH biosynthesis *in vitro* were mirrored by changes in adenylyl cyclase activity (Granger *et al*., 2000). Thus, in this species, cAMP appears to be important in neurotransmitter effects on the CA.

Transduction of a neurotransmitter signal appears to be mediated by cAMP in the CA of adult male *L. migratoria* as well (Lafon-Cazal and Baehr, 1988). In this species, stimulation of JH biosynthesis by dopamine correlates with an increase in adenylyl cyclase activity. In honeybee larvae, both octopamine and serotonin elicit a dose-dependent increase in JH release from intraglandular stores of JH in the CA (Rachinsky, 1994). Incubation of these glands with the phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine (IBMX) and a threshold concentration of octopamine (10^{-8} M) potentiated the octopamine effect on JH release, indicating that the action of octopamine is mediated by cAMP.

3.7.7.4.2. Inositol phosphates and diacylglycerol Other possible candidates for the transduction of neuropeptide signals in insects are IP3 and diacylglycerol (DAG), which are products of phosphatidylinositol-4,5 bisphosphate hydrolysis. The binding of the neuropeptide to a cell membrane receptor, which then interacts with membrane-bound G proteins, initiates this cascade. Increased IP3 then elicits the release of Ca^{2+} from intracellular storage sites, while DAG activates protein kinase C (PKC) (Berridge, 1993). The IP3 second messenger pathway exists in insects (Berridge, 1993). Work by Feyereisen and Farnsworth (1987) demonstrated that phorbol esters, which activate PKC, are potent inhibitors of JH biosynthesis in *D. punctata*, suggesting this pathway as central to the transduction of the AST signal. In a subsequent study, Rachinsky *et al*. (1994) found that treatment of *Diploptera* CA *in vitro* with inhibitors of DAG kinase elevates the concentration of DAG, resulting in a significant, dose-dependent inhibition of JH biosynthesis. A further enhancement of this effect was obtained when the CA were exposed *in vitro* to both DAG kinase inhibitors and ASTs, suggesting that the DAG pathway is indeed involved in the cellular response to the AST signal. Treatment of the CA with thapsigargin, a drug that mobilizes calcium stores without generation of inositol phosphates, significantly stimulates JH biosynthesis by, and also reverses the effect of ASTs on, highly active CA from mated females. It does not affect inactive CA from virgin females. The authors concluded that IP3, the other product of phosphoinositide hydrolysis, could modulate JH biosynthesis at specific development time points and thus could be responsible for the decreasing sensitivity of the CA of mated females to ASTs (Stay *et al*., 1991b). Furthermore, the stage-specific effects of IP3 on intracellular free Ca^{2+} in turn modulate the antagonistic action of DAG (Rachinsky and Tobe, 1996).

In adult male and female *M. sexta*, Manse-AT induces the production of inositol phosphates, including IP3, in CA *in vitro*, and two intracellular Ca^{2+} releasing agents were found to stimulate JH biosynthesis *in vitro*, similar to the effect of Manse-AT (Reagan *et al*., 1992). On this basis, these investigators concluded that Manse-AT activates the IP3 pathway in adult *Manduca* CA, increasing the intracellular concentration of free Ca^{2+} and thus stimulating JH biosynthesis. Staurosporine, a PKC inhibitor, had no effect on the inositol phosphates, but did stimulate the rate of JH biosynthesis *in vitro* and indicated a role for DAG as well. DAG involvement must be confirmed and the mechanism of staurosporine-induced stimulation must be established.

3.7.7.4.3. Calcium Calcium is unique as a second messenger in the CA, in that a transmembrane channel is involved, which may open either in response to ligand–receptor binding or to a change in membrane potential. The resulting increase in cytosolic free Ca^{2+} then interacts with the same cascades of biochemical events as cyclic nucleotides and inositol phosphates. While JH biosynthesis by *Diploptera* CA *in vitro* can be stimulated by the release of intracellular Ca^{2+} stores (Rachinsky *et al*., 1994; Rachinsky and Tobe, 1996), it appears that calcium stimulation of JH production occurs primarily by its influx from the extracellular environment. Calcium was first indicated as a player in the control of JH biosynthesis in *D. punctata* with the observation that elevated extracellular Ca^{2+} substantially reduces the effects of brain extract (ASTs) on JH biosynthesis (Aucoin *et al*., 1987). It was then shown that JH synthesis is nearly totally inhibited in Ca^{2+}-free medium but is stimulated in media with increasing concentrations of this ion (Kikukawa *et al*., 1987). Studies by Thompson and Tobe (1986) indicated that Ca^{2+} acts as a second messenger to stimulate JH biosynthesis by entering CA cells through voltage-gated Ca^{2+} channels. Recent work by Chiang and colleagues demonstrated that another type of Ca^{2+}-permeable membrane channel is involved in regulation of JH production by Ca^{2+}; the receptor-operated, ionotropic L-glutamate receptor (Pszczolkowski *et al*., 1999; Chiang *et al*., 2002b).

Elevated Ca^{2+} concentrations in incubation medium stimulate the synthesis of JH *in vitro* by the ring glands of *D. melanogaster* (Richard *et al.*, 1990) and the larval blowfly *Lucilia cuprina* (East *et al.*, 1997), the larval CA of *M. sexta* (Allen *et al.*, 1992a), and adult male CA of the cricket *G. bimaculatus* (Klein *et al.*, 1993). By contrast, JH biosynthesis by the CA of *L. migratoria* appears to be relatively independent of changes in extracellular Ca^{2+}, although calcium ionophores can elicit and increase synthesis, depending on the physiological status of the adult source (gregarious but not solitary) (Dale and Tobe, 1988a).

With *M. sexta* CA, Ca^{2+} levels may vary with the stage of development. Larval CA were found to require extracellular Ca^{2+} $\geq$0.1 mM for maximal JH biosynthesis *in vitro*, while JH acid synthesis by glands taken after pupal commitment continues in the absence of extracellular Ca^{2+} (Allen *et al.*, 1992a). Both calcium ionophores and caffeine, which initiate the release of Ca^{2+} from intracellular stores, stimulate JH acid synthesis by postcommitment CA, suggesting that intracellular Ca^{2+} may be the principal source of this ion after commitment. Calcium channel antagonists and calcium channel blockers decrease JH biosynthesis by both larval and postcommitment CA, indicating that Ca^{2+} channels exist in the CA cell membrane and that these channels may be both voltage-gated and receptor-operated.

Measurements of cytosolic free Ca^{2+} in isolated *Manduca* CA cells by use of the fluorescent Ca^{2+} indicator Fura-2 and digitized microscopy revealed that the highest levels of intracellular Ca^{2+} occur on days 0 and 6 of the last stadium, when *in vitro* synthesis of JH and JH acid is at the highest levels (Allen *et al.*, 1992a, 1992b) (**Figure 12**). Concentrations of free Ca^{2+} in *Manduca* hemolymph peak on days 0 and 7 of the last stadium (Allen *et al.*, 1992a); thus, there is an optimal concentration of Ca^{2+} in the hemolymph at the time when the CA require extracellular Ca^{2+} for maximal synthesis. This finding suggests that extracellular free Ca^{2+} could be responsible, at least in part, for the high activity of the gland at this time. Furthermore, free cytosolic Ca^{2+} levels decrease significantly by day 1, when the hemolymph titers in JH have dropped precipitously (Baker *et al.*, 1987). However, the concentrations of free Ca^{2+} in the hemolymph throughout the last stadium never drop below millimolar concentrations (Allen *et al.*, 1992a). Thus, it is clear that free Ca^{2+} is a significant player in the control of CA biosynthetic activity, but probably as a partner to another signal. It is interesting that steroid hormones are known to stimulate Ca^{2+} influx in certain biological systems (Blackmore *et al.*, 1990) and that free Ca^{2+} is highest in the CA cells at times when the hemolymph ecdysteroid titer in *M. sexta* is high (Bollenbacher, 1988). Thus, another possible mechanism for interendocrine control of JH synthesis by ecdysteroids (see Section 3.7.7.3.2) could involve the calcium ion.

A similar approach to measuring free Ca^{2+} in isolated cells of *Diploptera* CA was used to study the effects of thapsigargin and Dippu-AST (Rachinsky and Tobe, 1996). It was found that thapsigargin elevated intracellular Ca^{2+}, confirming the stimulatory effect of thapsigargin on JH biosynthesis via elevated Ca^{2+}; this effect could not be blocked by the later addition of Dippu-AST. The simultaneous addition of Dippu-AST with thapsigargin prevented the thapsigargin-induced increase in intracellular Ca^{2+}, although, as mentioned previously, the inhibition of JH biosynthesis by Dippu-AST is abolished by thapsigargin (Rachinsky *et al.*, 1994). These conflicting results are not yet resolved.

It has been known for many years that the calcium ion also can act indirectly as a second messenger, by binding to calmodulin (CaM) and eliciting a conformational modification of CaM (see **Chapter 3.2**). This enhances the affinity of the Ca^{2+}/CaM complex for target effectors, such as membrane-associated and cytosolic enzymes and transmembrane ion channels, including that for Ca^{2+} (Stoclet *et al.*, 1987). It is of interest to note that a Ca^{2+}/CaM-sensitive adenylyl cyclase has been identified in the CA of *Manduca* last instars (Granger *et al.*, 1995b).

3.7.7.4.4. Potassium Postassium also affects JH biosynthesis. Treatment of adult female *L. migratoria* CA *in vitro* with high levels of K^+ stimulates JH biosynthesis, either by stimulating the release of ASTs from nerve endings within the CA or by a direct effect on the CA cells (Dale and Tobe, 1988a). A K^+-elicited inhibition of JH synthesis was also reported for *D. punctata* (Rankin *et al.*, 1986), but in both cases, the effect of high concentrations of K^+ proved to be Ca^{2+}-dependent because it was abolished by Ca^{2+} channel blockers (Dale and Tobe, 1988b).

In summary, based on the evidence to date, it appears that the allatotropic and allatostatic neurotransmitters, which are in evolutionary terms the more primitive intercellular signaling molecules, operate via cyclic nucleotide second messengers. The neuropeptidergic signals that evolved later are transduced by phosphoinositides and DAG. Calcium plays a central role in the function of both types

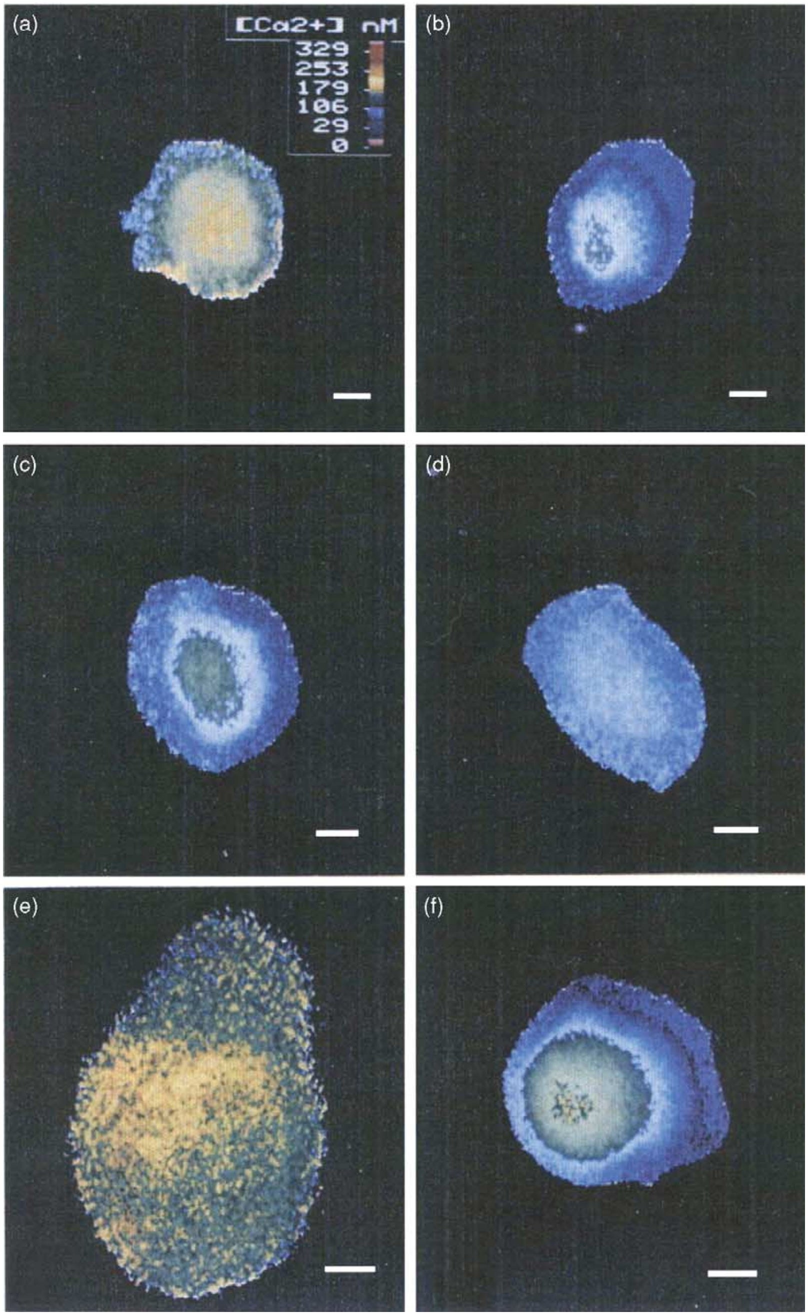

Figure 12 Measurements of cytosolic free Ca^{2+} in isolated *Manduca* CA cells. Pseudocolored ratio images of CA cells from fifth stadium larvae and early pupae. Cells loaded with Fura-2 and incubated in Grace's medium containing 0.1 mmol l^{-1} Ca^{2+}. (a) Day 0; (b) day 1; (c) day 2; (d) day 4; (e) day 6; (f) day 0 pupal period. The color spectrum in A corresponds to the concentration range (nmol l^{-1}) of Ca^{2+}. Scale bars represent 120 μm. Manipulation of intracellular calcium affects *in vitro* juvenile hormone synthesis by larval corpora allata of *Manduca sexta*. *Mol. Cell. Endocrinol. 84*, 227–241.)

of second messengers, and may itself contribute to the upregulation of gland activity at certain critical times when JH biosynthesis levels are high.

3.7.7.5. Putting It All Together

Given the long list of factors that can affect the biosynthetic activity of the CA, and perhaps also its product(s) – something that has not yet been explored, attempts to create an overall mechanism of endocrine control is fraught with hazards. An excellent summary of the roles of calcium and phosphoinositides in second messenger signaling in the regulation of JH production was made by Rachinsky and Tobe (1996), using three different

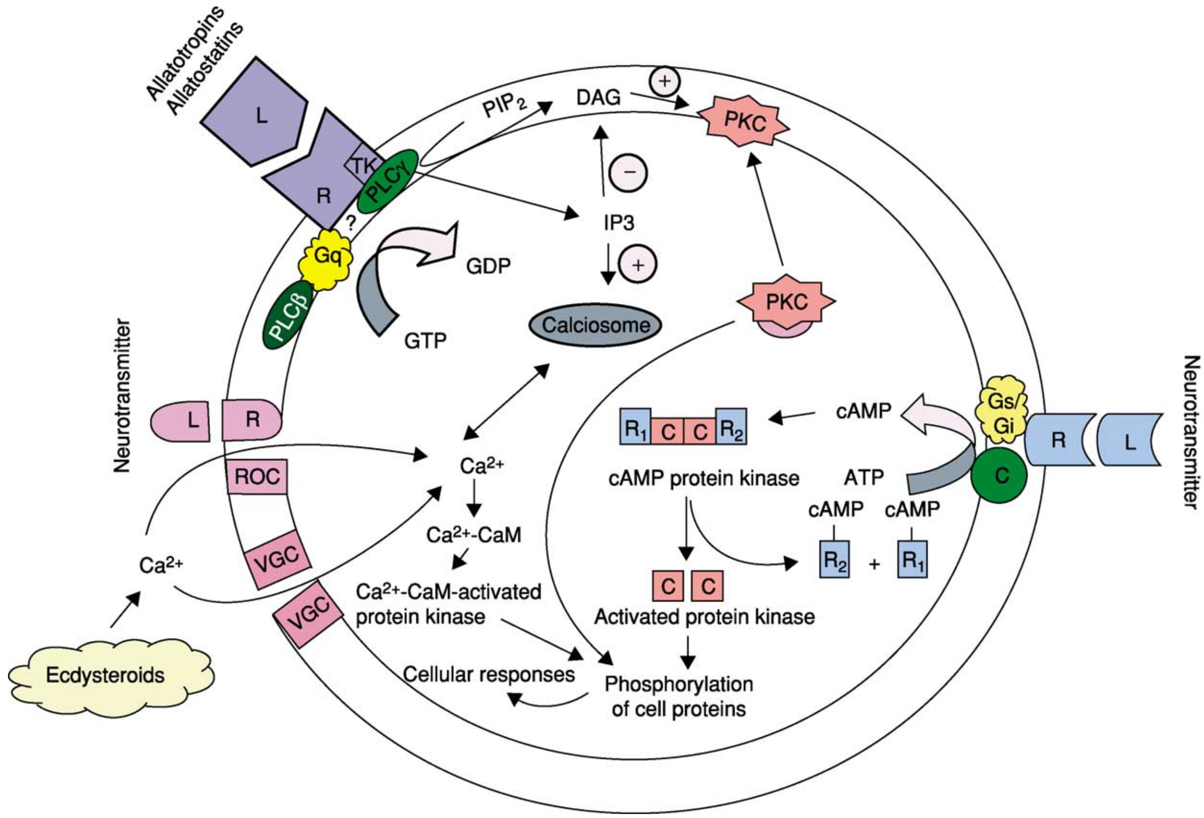

Figure 13 Hypothetical scheme for the regulation of JH biosynthesis by the CA. Factors thought to be involved include neurohormones, neurotransmitters, ecdysteroids, and second messengers. L, ligand; R, receptor; ROC, receptor-operated channel; VGC, voltage-gated channel; c, catalytic subunit; $R_{1,2}$, regulatory subunit; C, cyclase; G_s, stimulatory G protein; G_i, inhibitory G protein; G_q, G protein associated with phospholipase C; PKC, protein kinase C; DAG, diacylglycerol; IP3, inositol triphosphate; PIP_2, phosphatidylinositol-4,5 bisphosphate; TK, tyrosine kinase; PLC, phospholipase C.

insects as model systems: *L. migratoria*, in which JH biosynthesis appears to be governed principally by allatotropic signals; *D. punctata*, where this role is filled by ASTs; and *M. sexta*, in which both types of signals occur, perhaps as the result of the complex nature of the products of the CA in this species and possibly coupled with its holometabolous development. They concluded that differences in signal transduction between species reflect, in part, differences in the signals themselves, and that these differences may be stage-specific.

With the complicated nature of this discussion, which excludes a consideration of signals other than neuropeptides, neurotransmitters, and selected hormones, we have chosen to create a scheme for a CA cell that is representative of all insects, responding to these various types of signals and containing all of the second messenger systems shown to exist thus far (Figure 13). Thus, this cell responds to ATs and ASTs, neurotransmitters, ecdysteroids, and Ca^{2+}, operating via either voltage-gated or receptor-operated channels. It contains adenylyl cyclase, phosphoinositide/DAG, and Ca^{2+} second messenger systems, involving PKC. The complexity of this scheme indicates how much work is yet to be done on the basic mechanisms regulating JH biosynthesis at the level of the gland.

3.7.8. Hemolymph Transport Proteins for the Juvenile Hormones

The physicochemical nature of JH presents the insect with a serious problem, that of dispersing a lipid hormone via an aqueous circulatory system. While the JH homologs are water-soluble at levels that far exceed the physiological titers normally encountered (Kramer *et al.*, 1976), their amphiphilic nature promotes surface binding (Law, 1980). When dispersed in an aqueous medium, JH displays a marked propensity for nonspecific binding to nearly any surface, making its distribution problematic. Early in the evolution of insects and crustaceans, hemolymph proteins arose that interacted with JH in a noncovalent fashion, yet allowed them to be dispersed in the aqueous environment of the hemolymph (Li and Borst, 1991; King *et al.*, 1995). These

transport proteins, with their hitch-hiking hormones buried in a hydrophobic pocket, provided early arthropods with a readily available source of hormone that could dissociate from the protein and interact with target tissues. These transport molecules have evolved into highly specific hormone carriers that have been extensively studied since their discovery in the 1970s (Trautmann, 1972; Whitmore and Gilbert, 1972).

The hemolymph of most insect species contains two classes of JH-binding macromolecules: (1) non-specific binding molecules characterized by a high equilibrium dissociation constant ($K_d = >10^{-6}$ M; low affinity), and (2) specific binding molecules exhibiting a low equilibrium dissociation constant ($K_d = <10^{-6}$ M; high affinity) (Goodman, 1990). JH binding proteins of both types have been reported in approximately 50 species (Goodman, 1983; Goodman *et al*., 1991; Trowell, 1992). The association of JH with low affinity proteins may be biologically irrelevant, given the surface active nature of the hormone and the high probability of its metabolism. Examples of low affinity interactions between JH and proteins can be observed when photoaffinity-labeled JH probes are incubated *in vitro* with hemolymph proteins (Prestwich, 1987; Prestwich *et al*., 1994). In contrast to the low affinity binders, the high affinity JH binding proteins have captured considerable experimental attention, and it is these hemolymph proteins that will be discussed.

3.7.8.1. High Affinity, High Molecular Weight Hemolymph Juvenile Hormone Binding Proteins

The circulatory system of a number of insect species contains high affinity, high molecular weight hormone binding proteins, here termed hemolymph juvenile hormone binding proteins (hJHBP) to distinguish them from intracellular hormone binding proteins. Their high molecular weight appellation stems from the fact that the native molecular weight of these binding proteins routinely exceeds 300 kDa. The high molecular weight hJHBPs can be divided into two subgroups, the lipophorins and the storage proteins or hexamerins. These proteins were originally considered low affinity binders but more recent evidence, using the appropriate homologs and enantiomers, indicates the affinity is much higher than first reported (Trowell, 1992; deKort and Granger, 1996).

3.7.8.1.1. Larval lipophorins as juvenile hormone transporters Lipophorins are multimeric hemolymph proteins that transport dietary lipids, pheromones, and cuticular lipids to their sites of utilization (Soulages and Wells, 1994). These multifaceted transport proteins also transport JH in a number of insect species belonging to an evolutionarily diverse array of insect orders, including Dictyoptera, Isoptera, Coleoptera, Diptera, and Hymenoptera. Trowell (1992) examined this area extensively and we here focus briefly on lipophorin–JH transport proteins studies that have been reported since that review.

Much of the recent work on JH–lipophorin interaction has centered on the adult insects, and as noted by King and Tobe (1993), the information derived from the adult stage may not be applicable to the larval stage. Indeed, the situation in adults becomes more complicated as both lipophorins and vitellogenins interact with JH during the adult stage (Engelmann and Mala, 2000). Nevertheless, if one assumes that immunological identity between lipophorins of the nymphal and adult stages indicates these proteins have a similar if not identical structure (King and Tobe, 1993), then various characteristics of the larval JH binding lipophorin (JHBL) can be extrapolated from those of the adult. The JHBL from the adult female *D. punctata* is a multimer of 680 kDa, composed of subunits of apolipophorin I (230 kDa) and apolipophorin II (80 kDa) (King and Tobe, 1988). Covalent labeling with a JH III photoaffinity probe indicates that the binding site resides on the larger subunit only. The protein appears to be specific for the naturally occurring enantiomer (10*R*)-JH III and displays a dissociation constant of 3 nM (King and Tobe, 1988). These binding characteristics, high affinity, and selectivity towards the correct enantiomer are in keeping with the JHBLs from other species (Trowell, 1992; deKort and Granger, 1996). Since lipophorin levels in the hemolymph are typically high, ranging from 6 to 16 mg ml^{-1} during the last nymphal stadium (10-40% of the total hemolymph protein), titers of the transporter are significant and yield a large excess of unoccupied binding sites (King and Tobe, 1993). These investigators also confirmed that JHBL offers protection from enzymatic degradation. As might be expected, titers of the JHBL follow total hemolymph protein levels, with a notable exception approximately one-third of the way though the stadium. At this time, levels of JHBL jump from 4 mg ml^{-1} to 12 mg ml^{-1} with no corresponding increase in total hemolymph protein. An even larger rise in JHBL is noted during a corresponding period in *L. maderae* (Engelmann and Mala, 2000). Unfortunately, the rapid increase in titer has yet to be linked to any biological event.

Trowell *et al.* (1994) characterized a JHBL in the hemolymph of larval *L. cuprina*. As is the case with other JHBLs, the blowfly protein is composed of two types of subunits, apolipohorin I (228 kDa) and apoliphorin II (70 kDa). Binding studies indicate that JH III is the preferred homolog followed by JH II > JH I > JH III acid > JH diol. Curiously, no displacement is observed with JHB_3 even though it is the predominant *in vitro* product of the blowfly CA (Trowell *et al.*, 1994). The dissociation constant for JH–JHBL is approximately 30 nM and, as with the other JHBLs studied to date, the fat body is the site of synthesis.

3.7.8.1.2. Larval hexamerins as juvenile hormone transporters A second type of high affinity, high molecular weight JH transport molecule has been discovered, having the characteristics of a hexamerin. The hexamerins, composed of six 70–80 kDa subunits, are widely distributed throughout the phylum Arthropoda and have been found in insects, crustaceans, and certain chelicerates (Burmester, 2002); however, they are not typically employed as hemolymph JH transporters. To date, only species in the order Orthoptera, including *L. migratoria* (Koopmanschap and deKort, 1988; Braun and Wyatt, 1996) and *Melanoplus sanguinipes* (Ismail and Gillott, 1995), are known to exploit hexamerins as JH transport proteins.

The most thoroughly studied of the JH-binding hexamerins (JHBHs) is that of *L. migratoria*. This protein, a 74.4 kDa protein, as deduced by cDNA analysis (Braun and Wyatt, 1996), contains 15% lipid (Koopmanschap and deKort, 1988). Binding analysis indicates the dissociation constant for (10*R*)-JH III–JHBH is 1–4 nM. According to Koopmanschap and deKort (1988), the hexamerin is present at relatively low concentrations that never exceed 2% of the total hemolymph protein, yet its hexameric structure allows a single native molecule to bind up to six molecules of hormone. As a result, this JHBH contains very large number of unoccupied hormone binding sites. The 4.3 kb hexamerin mRNA encodes a 668 amino acid protein and contains 2 kb of 3′ untranslated region (GenBank Accession no. U74469) (Braun and Wyatt, 1996). Functional assays to locate the JH binding site suggest that it resides in the N-terminus, since a truncated JHBH lacking this region does not bind the hormone. A comparison of its amino acid sequence with other members of the hexamerin superfamily indicates that the JHBH from *L. migratoria* represents a new form that is most closely aligned with the hemocyanins (Braun and Wyatt, 1996).

3.7.8.2. High Affinity, Low Molecular Weight Hemolymph Juvenile Hormone Binding Proteins

While the high affinity, low molecular weight hJHBPs are limited to only Lepidoptera and Diptera (review: Trowell, 1992), they have, nevertheless, been characterized extensively because relatively large quantities of larval hemolymph can be easily obtained from just a few insects. The low molecular weight hJHBPs are usually monomeric and range in molecular weight from 25 to 35 kDa. Although low molecular weight hJHBPs have been identified in a number of lepidopterans, only those in *B. mori*, *G. mellonella*, and *M. sexta* have been extensively studied.

3.7.8.2.1. Chemical and physical characteristics The lepidopteran hJHBPs are monomers composed of approximately 220–240 amino acid residues. In species where the primary sequence of hJHBP has been deduced, four to six cysteine residues have been reported. *Manduca sexta* hJHBP, which has six cysteine residues (Park and Goodman, 1993) and *G. mellonella* hJHBP, which has four cysteine residues (Kolodziejczyk *et al.*, 2001), contain two disulfide bridges.

The results of CNBr cleavage, together with extrapolated data from the study of *G. mellonella* hJHBP, suggest that the disulfide bridges in *M. sexta* hJHBP are probably formed from the Cys9 to Cys16 and Cys151 to Cys195 residues. That the cysteine residues at position 9 and 16 are important to JH binding was demonstrated with the *H. virescens* hJHBP. This hJHBP displays a nearly identical alignment of cysteine residues with those in the *M. sexta* hJHBP (Wojtasek and Prestwich, 1995). Using the *H. virescens* hJHBP construct, Wojtasek and Prestwich (1995) generated mutant hJHBPs in which an alanine was substituted for a cysteine residue at each of the cysteine positions. They discovered that Cys9 and Cys16 are critical for JH binding but that cysteine residues at other sites are much less important. Park and Goodman (1993) demonstrated that of the two remaining cysteine residues not involved in disulfide bond formation, one is inaccessible to alkylating agents, implying an internal location within the protein. The other cysteine residue is easily modified, suggesting a location on the surface of the protein. The role of disulfide bridges in overall structure and hormone binding has yet to be determined.

Initial studies indicated that the *M. sexta* hJHBP is not glycosylated (Goodman *et al.*, 1978a); however, more recent evidence suggests hJHBPs from both

G. mellonella and *M. sexta* are indeed glycosylated. Using matrix assisted laser desorption ionization time of flight (MALDI-TOF) measurements to determine the molecular mass of the native protein and to calculate the deduced amino acid residue mass, it has been determined that carbohydrates account for approximately 10% of the molecular mass of the *M. sexta* hJHBP (Goodman, unpublished data). Computer analysis of potential glycosylation sites indicates only one potential motif, that surrounding the Asn66 residue of the mature, secreted protein. The carbohydrate moiety can be enzymatically cleaved from the hJHBP using *N*-glycosidase F; however, hJHBP is resistant to cleavage by other glycosidases such as neuraminidase and endoglycosidase H (Goodman, unpublished data). Computer analysis of potential glycosylation motifs in the hJHBP from *G. mellonella* indicate multiple sites for glycosidation, including an *O*-GalNAc site (Thr116), *N*-glycosylation sites (Asn3, Asn93) and *O*-β *N*-acetylglucosamine (*O*-βGLcNAc) sites (Ser12, Thr116, Thr186) (Duk *et al*., 1996). Duk *et al*. (1996) confirmed this observation using lectin binding assays, gel staining, and mass spectrometry and suggested there are five major types of oligosaccharide chains, each containing two GlcNAc residues and two, three, or five mannose residues. The function of these carbohydrate moieties is unknown; however, glycosylation of hormone transport proteins in vertebrates is thought to limit proteolytic cleavage of the protein and thereby increase its half-life in the circulatory system (Westphal, 1986). While other potential posttranslational modifications can be predicted from computational programs, no experimental evidence for the modifications has been reported.

The lepidopteran hJHBPs interact with their ligands at concentrations in the low nanomolar range (Goodman, 1990; Trowell, 1992; deKort and Granger, 1996); however, the homologs are not all bound with the same affinity. It was originally thought that the least polar of the homologs was bound with the highest affinity (Goodman *et al*., 1978b), following the polarity rule which states that within a series of small nonpolar homologous hormones, the least polar of the group will be bound with the highest affinity (Westphal, 1986). Park *et al*. (1993), in an extensive study of *M. sexta* hJHBP binding kinetics, demonstrated that the polarity of the JH homologs was not as important to the binding equilibrium as first proposed. This study revealed that the dissociation constants for the binding protein hormone complex are approximately the same for JH I or II, but as previously observed, the interaction with JH III is considerably weaker. Although the polarity rule may not apply to the equilibrium constants, it is quite clear that the more polar the homolog, the shorter the half-life of the hormone–protein complex (Park *et al*., 1993). Thus, JH I, the least polar of the homologs tested, has the longest half-life (29 s), while JH III, the most polar homolog, has the shortest (13 s). These half-times of dissociation are consistent with vertebrate hormone transport proteins (Mendel, 1989).

The hJHBP of *M. sexta* preferentially binds the naturally occurring enantiomers of (10*R*)-JH III (Schooley *et al*., 1978b), (10*R*,11*S*)-JH I, and (10*R*, 11*S*)-JH II (Park *et al*., 1993). This enantiomeric specificity appears universal among the high affinity JH binding proteins, whether they are lipophorins or hexamerins (Trowell, 1992; deKort and Granger, 1996), indicating the binding site for the hormone is reasonably selective.

In addition to binding studies using the JH homologs and their respective enantiomers, studies have been conducted using geometrical isomers of the hormones, hormone metabolites, and biologically active analogs (Goodman *et al*., 1976; Peterson *et al*., 1977, 1982). The results indicate that highly active JH analogs and JH metabolites do not interact with hJHBP. Armed with this information, several investigators have speculated on the nature of the ligand binding domain and its constituent residues. Goodman *et al*. (1978b) suggested the binding site may be a hydrophobic cleft on the surface of the protein. The primary interactions between the hormone and the binding site would occur along the alkyl side chains of the hormone and the methyl ester moiety at C1, which together form a distinct hydrophobic surface. Perturbation of that surface, especially by the introduction of highly polar groups at C1, significantly reduces binding. However, the site is not sterically hindered since nonpolar additions such as ethyl and propyl groups at the C1 position reduce binding only moderately (Peterson *et al*., 1977). Hydrogen bonding, which involves electrophilic residues in the binding site, potentially anchors the hormone at the epoxide and C1 positions and may be more important for interaction with JH III than JH I. Support for this idea comes from the studies of Prestwich and Wawrzeńczyk (1985), who found that the interaction between the naturally occurring JH I enantiomer and hJHBP was only several fold greater than its antipode, suggesting that the binding site could not only accommodate the 10*R*,11*S* enantiomer but the 10*S*,11*R* enantiomer as well. In contrast, the significant binding energy derived from the (10*R*)-JH III epoxide–hJHBP interaction is probably disrupted in the (10*S*) configuration. Thus, the reduction in

the hydrophobic "face" of JH III places considerably more importance on the hydrogen bonding between the epoxide and methyl ester of JH III and the hJHBP.

Using photoaffinity labeling, Touhara and Prestwich (1992) attempted to map the binding site of the *M. sexta* hJHBP. On the basis of labeling patterns, they proposed that the region from Ala184 to Asn226, a region predicted to be a hydrophobic domain, is involved in the recognition of the lipophilic backbone of JH. Another region, Asp1 to Glu34, also appears to be involved, leading these investigators to propose a model in which the two regions are connected by disulfide bridges to form a two-sided hormone binding pocket. More recently, Tesch and Goodman (unpublished data) discovered that trypsin treatment of hormone-saturated (holo-hJHBP) and hormone-free hJHBP (apo-hJHBP) from *M. sexta* yields strikingly different results, raising questions about the Touhara and Prestwich model. When holo-hJHBP is treated with trypsin, the C-terminus of hJHBP from Lys180 onward is rapidly removed. The N-terminus (first 180 residues) of the molecule remains intact for approximately 1 h, despite the fact that it contains at least 10 well-documented tryptic cleavage sites. The trypsin-truncated hJHBP is still capable of binding JH, indicating that the C-terminus (last 46 residues) of the protein, despite its elevated level of hydrophobicity, is not directly involved in binding. Conversely, apo-hJHBP, when treated with trypsin, is completely destroyed within a few minutes. Similar findings were observed in *G. mellonella* (Wieczorek and Kochman, 1991). These results suggest that the binding site is not located in the C-terminus as proposed by the Touhara and Prestwich model but rather lies upstream, closer to the N-terminus. Rodriguez-Parkitna *et al.* (2002) hypothesize that the C-terminus may serve as a "barrel cover" that changes its position upon hormone binding. Thus, while the C-terminus may not be directly involved in hormone binding, it may have other important roles, such as target cell docking functions or hormone transfer to the cell.

Hormone-induced conformational changes have been observed in certain of the vertebrate serum steroid hormone binding proteins (Grishkovskaya *et al.*, 2002), and there is good evidence indicating that hJHBP undergoes a conformational change upon interaction with JH, but the degree of change appears to vary with the species. While the hormone appears to induce conformational changes that mask certain regions, no differences were detected between apo- and holo-hJHBP in sedimentation rate or electrophoretic migration studies in *M. sexta* (Tesch and Goodman, unpublished data). The studies of Touhara *et al.* (1993) on recombinant *M. sexta* hJHBP did not reveal differences in circular dichroism spectra of apo- and holo-hJHBP, indicating that the hormone does not induce changes in secondary structure. In contrast to these studies, Wieczorek and Kochman (1991) demonstrated a shift in the sedimentation coefficient between the apo-hJHBP (2.30S) and holo-hJHBP (2.71S) forms of the hJHBP from *G. mellonella*, as well as slight changes in electrophoretic mobility between these two forms. More recently, the Kochman group used circular dichroism analyses to confirm their earlier discovery that hormone binding leads to changes in the secondary structure of hJHBP in *G. mellonella* (Krzyzanowska *et al.*, 1998). It is unclear why these changes in secondary structure were not detected in the *M. sexta* hJHBP. It may well be that small but significant differences between the primary and secondary structures of the *M. sexta* and *G. mellonella* hJHBPs are responsible. These initial studies on ligand-induced conformational change are highly intriguing but unfortunately offer only a glimpse into the structure and dynamic conformational changes. Crystallographic studies, such as those currently under way with the *G. mellonella* hJHBP (Kolodziejczyk *et al.*, 2003) will provide the desired information on the nature of the JH binding site and ligand-induced conformational change in the protein.

3.7.8.2.2. Protein structures The high affinity, low molecular weigh hJHBPs that have been sequenced to date display a reasonable degree of identity in alignment (~25%), but as noted by Rodriguez-Parkitna *et al.* (2002), no one region shows a higher than average homology, thus precluding the identification of a putative JH-binding domain (**Figure 14**). These investigators examined other JH-associating proteins for potential sequence similarities and concluded that there was little similarity among the hJHBPs and ligand binding domains of potential nuclear receptors, insect transferrins, or the high affinity, high molecular weight JHBPs. From this analysis, it may be inferred that the composition and sequence(s) of amino acids residues making up the hydrophobic JH binding domain are not under extreme selective pressure, as long as the site is lined with hydrophobic residues that permit interaction with the aliphatic side chains of the hormone. However, the site must contain the hydrophilic residues to permit interaction with the epoxide moiety.

As more protein sequences enter the data bases, a picture is emerging that suggests the lepidopteran

Figure 14 Multiple alignment of the sequenced hemolymph JH binding proteins (hJHBPs) from Lepidoptera. Amino acid sequences of *M. sexta* (Madison wild-type) hJHBP (GenBank Accession no. AAF45309), *B. mori* hJHBP 2 (AAF19268), *H. virescens* hJHBP (AAA68242), and *G. mellonella* hJHBP (AAN06604). Alignment was performed using the CLUSTAL W algorithm. Letters in bold represent residues in the signal peptide. Symbols beneath the columns of amino acid residues represent the degree of conservation in each column: (*) indicates residues completely conserved; (:) indicates residues with only very conservative substitutions; (.) indicates residues with mostly conservative substitutions.

hJHBPs belong to a superfamily of proteins, the calycins (Rodriguez-Parkitna *et al.*, 2002), which include fatty acid binding proteins, avidins, lipocalins (see **Chapter 4.8**), and metalloprotease inhibitors (Flower, 1996, 2000). Proteins in this family are typically low molecular weight, secreted proteins that bind small, hydrophobic molecules. Members of the calycin protein family share a β-barrel structure composed of 8 or 10 β-sheets that are flanked by α-helices in the N- and C-termini. While sequence similarity between the hJHBPs and other members of the superfamily is low, modeling of the *G. mellonella* and *M. sexta* hJHBP secondary structure indicates considerable similarity to insecticyanin and human plasma retinol binding protein, both well-studied lipocalins (Rodriguez-Parkitna *et al.*, 2002). Given the structural information gleaned to date, it will not be surprising if in the near future, the lepidopteran hJHBPs are firmly placed in the lipocalin subfamily of calycins.

3.7.8.2.3. Genomic structures At the present time, the genomic structure of only one *hJHBP*, that from *M. sexta* (Madison wild-type strain), has been examined (Orth *et al.*, 2003a). The *hJHBP* locus (GenBank Accession no. AF226857) consists of five exons spanning 6.7 kb and is flanked by typical eukaryotic and insect-specific transcriptional control elements. The first exon encodes the 5′ untranslated region, a signal peptide plus the first two amino acids of the open reading frame, while the other exons encode the mature, secreted protein and the 3′ untranslated region. The proximal promoter region contains a A/T-rich region similar in position, but slightly longer than that of the JH esterase gene from *T. ni* (Jones *et al.*, 1998); however, both of these genes lack the canonical TATAA motif normally associated with the proximal promoter region. Computational analysis indicates numerous potential transcription factor binding sites in the 5′-flanking region of the gene. Most intriguing are

two closely spaced ECR response elements (see **Chapter 3.5**) approximately 5 kb upstream from the start site. The JHs are presumed to act on the ecdysteroid signaling pathway (Riddiford, 1994), regulating gene expression by modulating the transcriptional activity of the ecdysteroid receptor and its heterodimeric partner, Ultraspiracle (Jones and Sharp, 1997) (see Section 3.7.12.2). Considering that both the protein concentration (Hidayat and Goodman, 1994) and the *hJHBP* gene expression (Orth *et al*., 1999) undergo a significant decline during a larval-to-larval molting period, it is reasonable to speculate that ecdysteroids, acting via these ecdysteroid response elements, may be involved in the regulation of *hJHBP* expression and may indirectly modulate JH titers.

Recent studies reveal that strain-related polymorphisms in the *hJHBP* nucleotide sequence, outside the open reading frame, lead to significant differences in the titers of this protein. A comparison of hJHBP levels in two different strains of *M. sexta* revealed that one strain, the Seattle wild-type (*Swt*), has levels that are nearly 60% lower than those of the Madison wild-type strain (*Mwt*) (Young *et al*., 2003). The *Swt* strain exhibits an *hJHBP* allele, *Snb*, that differs significantly from the previously described *Md* allele found in the *Mwt* strain (Orth *et al*., 2003a) by the presence of a novel insertion in intron 2. The relatively small size of the insert (<500 bp), its position between direct repeats, its integration into an A/T rich region, and its lack of an open reading frame all suggest that the element is similar to a small, integrated nuclear element (Adams *et al*., 1986; Robertson and Lampe, 1995; Jurka and Klonowski, 1996). This element, termed Ms1, is abundant in the genome of *Mwt* (Young *et al*., 2003); however, the *Md* gene locus of the strain does not contain Ms1. While lepidopteran insertion elements are not particularly novel, the effect of Ms1 on *Swt* expression of *hJHBP* is significant. A potential mechanism by which *Snb* may depress hJHBP titers can be deduced from the sequence of Ms1. Zhou and Liu (2001) report that sequences within the *B. mori* repetitive insertion element Bm1, termed matrix-associating regions (MARs), interact differently with the nonchromatin scaffolding than do insertion elements lacking MARs. The insertion of MARs into a gene or locus may have significant effects on gene expression by hindering DNA unwinding during transcription (Walter *et al*., 1998; Carey and Smale, 2000); thus, expression of hJHBP by the *Swt* strain may be downregulated by this unique insertion element. From the physiological standpoint, the reduced levels of hJHBP in individuals expressing the *Snb* gene locus appear to have negligible effects on JH titers at hour 50 of the fourth stadium, the only time point examined in this study. Due to the high levels of hJHBP in wild-type animals (Hidayat and Goodman, 1994) and the high affinity of hJHBP for JH (Park *et al*., 1993), it may well be that the insect can withstand a loss of as much as 60% of the circulating hJHBP and still maintain levels of the hormone sufficient to prevent metamorphosis. The discovery of Ms1 serves as a warning that laboratory strains of the same species, held in reproductive isolation for long periods of time, are rapidly diverging from their common ancestor. The belief that all wild-type strains of the same species will respond to physiological challenges in an identical fashion may be a naive assumption.

3.7.8.2.4. Regulation The discovery of the high affinity JHBPs naturally leads to the question of whether these proteins have a direct influence on JH titers. In most insects, the exceedingly high ratio of hJHBP to JH makes it unlikely that even significant shifts in hJHBP levels would play a direct role in hormone regulation (Hidayat and Goodman, 1994). As noted above, a 60% reduction in hJHBP titers in a strain of *M. sexta* does not markedly affect JH titer. Nevertheless, the hJHBP titers fluctuate significantly during development (Goodman, 1990; Hidayat and Goodman, 1994; Rodriguez-Parkitna *et al*., 2002), and these changes do not mirror the changes in total hemolymph protein levels. Assessment of bound and unbound hormone levels indicates that virtually all of the hormone is bound at any given time and that the level of holo-hJHBP is a tiny fraction of apo-hJHBP. Why should the fat body, the site of synthesis of hJHBP (Nowock *et al*., 1975), be engaged in excessive synthesis of this protein, and why should its levels be so precisely controlled? The presence of excess hJHBP remains a mystery, but one intriguing hypothesis suggests that the protein acts as a high affinity scavenger to sequester the hormone in the hemolymph where it can be metabolized by hemolymph enzymes (Touhara *et al*., 1996). This scavenger hypothesis has also been proposed for the role of hJHBP in the embryo, where maternal JH may need to be compartmentalized to prevent interference with embryonic development (Orth *et al*., 2003b). While this hypothesis is provocative, it assumes that cellular degradation of the hormone is minimal, and as noted below (see Section 3.7.9.1), this may not be the case.

Although it is unclear why the levels of hJHBP need to be controlled so precisely during development, a picture of the elements controlling the

expression of its gene is beginning to emerge. As previously noted, the presence of ecdysteroid response elements in the 5′ flanking region of *hJHBP* suggests ecdysteroids may be involved in the regulation of *hJHBP* expression. Conversely, there is reasonably good evidence that JH itself has a role in regulating the expression of this gene. It has been observed that an inverse relationship exists between JH and hJHBP titers in *M. sexta* (Hidayat and Goodman, 1994). Hormone titers at the beginning of the penultimate stadium are high, but hJHBP titers are low. When JH titers drop during the late intermolt period, levels of hJHBP rise (Hidayat and Goodman, 1994). Topical application of JH during the late intermolt period leads to a striking fivefold increase in hJHBP mRNA, beginning approximately 2 h after hormone application and persisting for approximately 18 h (Orth *et al*., 1999). The response is both dose-dependent and saturable, with higher levels of JH (>1 ng) inducing a downregulation of hJHBP mRNA abundance. Curiously, hormone application at other times during the stadium does not elicit this response, which has lead to the suggestion that JH-induced transcription of *hJHBP* is already maximally stimulated at these times and further elevation of hormone levels by topical application has a dampening response. Thus, the control of hJHBP levels appears to be tied to fluctuating JH titers during the intermolt period; elevated titers of the hormone downregulate hJHBP mRNA and protein, while reduced JH titers elevate both message and protein. During the molting period, the elevated levels of ecdysteroids required for molting reduce expression of the *hJHBP* gene. If the sole function of hJHBP is hormone delivery, then the developmental pattern and excess titer remain a mystery, but as with the vertebrate serum hormone binding proteins, the hJHBPs may be more than transport macromolecules.

3.7.8.3. Functions

Facilitating the transport and dispersal of JH to distant target sites is the most obvious function of the hJHBPs, yet other equally important roles for the binding protein have been hypothesized or experimentally determined (Westphal, 1986; Goodman, 1990). These functions include: (1) reducing the levels of promiscuous binding to nontarget tissues; (2) reducing enzymatic degradation of the hormone (Hammock *et al*., 1975); (3) acting as a scavenger to enhance JH metabolism in larval hemolymph (Touhara *et al*., 1996) or the developing embryo (Orth *et al*., 2003b); (4) providing a peripheral reservoir of hormone that is readily available at the target tissue; (5) enhancing JH synthesis in the CA by acting as a sink; and (6) aiding hormone movement from the hemolymph into the target cell. The first four functions are either well established or have at least gained a level of scientific credibility.

Preliminary evidence now suggests that hJHBP may promote the synthesis of JH by dispersing the hormone from the immediate vicinity of the CA. Using the RCA to assess the effect of several JH-interacting proteins (bovine serum albumin, JH-directed antiserum, and *M. sexta* hJHBP) on JH biosynthesis *in vitro*, it was observed that only hJHBP significantly increased the incorporation of radiolabeled tracer into JH (Granger and Goodman, unpublished data). *Manduca sexta* CA synthesized ~60% more JH when incubated in medium containing physiological levels of hJHBP. While the results are preliminary, they do suggest that the binding proteins aid the transit of JH from the CA and thus could prevent hormone from accumulating nonspecifically in the vicinity of the glands. The binding proteins, in essence, create a longer feedback loop and thus block short-circuiting of JH biosynthesis.

The most intriguing unexplored aspect of the hJHBP functions is that of its action at the surface of a target cell. A considerable body of evidence has convinced most vertebrate endocrinologists that hormone binding proteins release their ligands into the circulatory system, thus allowing them to enter the cell in the unbound state (Westphal, 1986; Mendel, 1989; Grasberger *et al*., 2002). For some hormones, this is a reasonable conclusion; however, several protein-bound hormones and vitamins have specific cell surface receptors for their respective transport proteins (review: Kahn *et al*., 2002). Retinol binding protein (RBP), for example, binds to a plasma membrane receptor that participates in transfer of the ligand from the serum transport protein to the cytoplasmic retinol binding protein (Sundaram *et al*., 1998, 2002). As levels of apo-RBP far exceed those of the holo-RBP, a conformational change in the protein must occur so that cell surface receptors are not interacting with ligand-free RBP (Chau *et al*., 1999).

Even more striking are the roles of sex hormone binding globulin (SHBG), a vertebrate serum protein that binds and transports the sex steroids. As is the case for RBP, target tissues requiring the sex steroids display a plasma membrane receptor for SHBG. Unlike the RBP receptor, the SHBG receptor binds only the unloaded form of the transport protein; the hormone-loaded SHBG complex does not bind (Kahn *et al*., 2002). Sex steroids then bind to the receptor-bound SHBG on the cell surface which, in turn, activates adenylyl cyclase. The role of the

activated second messenger cascade remains unknown. The extracellular transport protein is more than just a vehicle for hormone dispersal; indeed, it may need to be anchored at the cell surface to facilitate uptake. Moreover, the receptor–protein complex may have its own intrinsic signaling ability. Whether this complex cascade of hormone transfer, cell surface receptors, and activation of second messengers occurs in insects remains to be investigated.

3.7.9. Catabolism of the Juvenile Hormones

The maintenance of effective hormone titers at the target site is a delicate balancing act among various processes: synthesis, delivery, metabolism, and cellular uptake. Endocrine signals, by their very nature, must be transitory to effect their exquisite control of the target response. Soon after the chemical structures of JHs were elucidated in the late 1960s, a search for hormone-inactivating enzymes began that has continued unabated to the present, with better than 350 articles describing some aspect of JH metabolism. This prodigious number of publications reflects the agricultural interest in targeting catabolism as a means of insect pest control, since it is assumed that dramatically increasing or decreasing catabolism of JH may lead to developmental derailment (Bonning and Hammock, 1996). While this novel means of pest control has yet to be commercially exploited, the biological information gleaned from studies on JH metabolism is of considerable importance in understanding hormone titer regulation. For earlier reviews of JH catabolism, the reader is referred to Hammock (1985), Roe and Venkatesh (1990), deKort and Granger (1996), and Gilbert *et al*. (2000).

The initial step in JH catabolism may occur in the hemolymph or in target cells, and results in different products; however, the end point is the same: biological inactivation of the hormone. Hemolymph inactivation of JH is the result of enzymatic activity of several different esterases capable of hydrolyzing the hormone at the C1 position to form the metabolite, JH acid (Hammock, 1985; Roe and Venkatesh, 1990) (**Figure 2**). Although cellular inactivation of JH is primarily the result of epoxide hydrolases that hydrate the epoxide at the C10, C11 position to form the JH diol (**Figure 2**), cells also possess esterase activity that yields JH acid (Lassiter *et al*., 1995; Roe and Venkatesh, 1990). Our examination of JH catabolism begins with the hemolymph where esterases represent the primary mechanism of hormone inactivation.

3.7.9.1. Juvenile Hormone Esterases

The hemolymph of a number of species contains esterases that are capable of hydrolyzing the ester at the C1 position to form JH acid. While the early literature suggested that there are two classes of esterases responsible for JH hydrolysis, JH-specific esterase (JHE) and nonspecific or general esterases (Sanburg *et al*., 1975), recent work has been less clear about the role of the nonspecific enzyme(s) (Gilbert *et al*., 2000). General esterases were originally defined as those enzymes that could metabolize both a general substrate, α-naphthyl acetate, and JH (Sanburg *et al*., 1975) and were inhibited by the inhibitor *O*,*O*-diisopropyl phosphorofluoridate (DFP). More recent evidence suggests that the general esterases are less important in JH metabolism than first thought (Roe and Venkatesh, 1990; Gilbert *et al*., 2000).

Because conversion to JH acid can be carried out by a number of enzymes, Hammock (1985) proposed a working definition for a JHE. From a biochemical standpoint, such an enzyme should have a low apparent K_m for JH and it should therefore hydrolyze JH with a high k_{cat}:K_m ratio (see Section 3.7.9.1.2). Furthermore, the enzyme must be able to hydrolyze JH in the presence or absence of a JH binding protein. From a biological standpoint, the JHE must have activity that correlates with a decline in JH titer. The premise that these enzymes are vital to hormone titer regulation has thus received considerable attention.

3.7.9.1.1. Physical properties JH-specific esterases (EC 3.1.1.1) are members of the carboxylesterase family and have been studied in at least six orders of insects, including Thysanura, Orthoptera, Hemiptera, Coleoptera, Diptera, and Hymenoptera (Hammock, 1985); as molecular cloning becomes more widely used, more insect orders will undoubtedly be added to this list. To date, the best characterized of the JHEs are those from the hemolymph of Lepidoptera.

The JHEs of Lepidoptera appear to be composed of a single polypeptide chain with a relative molecular mass of approximately 63–67 kDa (Roe and Venkatesh, 1990; Hinton and Hammock, 2003). The hemolymph of the coleopteran *L. decemlineata*, contains a JHE with a native Mr of 120 kDa; it appears to be composed of two polypeptide chains of approximately 57 kDa each (Vermunt *et al*., 1997a). A similar situation exists in the orthopteran *Gryllus assimilis*, where the native JHEs displays a Mr of 98 kDa and is composed of two identical subunits of 52 kDa (Zera *et al*., 2002). The

isoelectric points of all the JHEs studied are acidic, falling into the range of 5.2 to 6.1 (Abdel-Aal and Hammock, 1986; Hinton and Hammock, 2003). Isoelectric focusing of apparently pure JHE from several species yields two to four distinct proteins, suggesting heterogeneity in posttranslational modifications such as glycosylation. The JHE of the lepidopteran *T. ni* is glycosylated (Hanzlik and Hammock, 1987); however, the JHE of *M. sexta* lacks glycosylation, even though computational analysis of its sequence indicates three potential glycosylation sites (Kamita *et al.*, 2003). It should be noted that even a baculovirus expression system containing a single JHE construct still yielded several isoforms that could not be explained by limited proteolysis or differential deglycosylation (Hinton and Hammock, 2003).

3.7.9.1.2. Kinetic parameters and specificity JHE kinetics and substrate specificity have long been a central focus of JHE studies, owing to the obvious agricultural potential of this information. Elucidation of JHE kinetic constants also permits predictions of the rate limits of JH metabolism, as well as provide valuable insight into to how peripheral JH levels are regulated. A number of reports from the 1980s indicate that among lepidopterans, the apparent Michaelis constant (K_m) for the naturally occurring JHs ranged from 10^{-8} to 10^{-6} M (Roe and Venkatesh, 1990). JH titers in the species tested are at least 10–100 times lower than the estimated K_m concentration, indicating that the enzyme is very sensitive to changes in JH concentration, but suggesting that its catalytic potential is wasted. Since the K_m values seem unduly high with regard to substrate concentration, investigators have examined the individual rate components of the enzymatic reaction to better explain the observed data (Sparks and Rose, 1983; Hammock, 1985; Abdel-Aal and Hammock, 1986).

In the simplest of terms, the velocity of JHE or any enzymatic reaction can be viewed as the sum of various rate components and the concentration of the reactants, and can thus be defined by the familiar equation:

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P \qquad [1]$$

where E represents enzyme, S represents substrate, ES represent the Michaelis complex, and P the product. Under physiological conditions, where the concentration of JH is several orders of magnitude lower than the K_m, the rate at which JH acid is formed is a function of JH interaction with JHE (k_1 and k_{-1}) and the rate of product formation (k_2). Several important lessons can be drawn from the kinetic data for JHE. First, JHE has a very high affinity for JH. Second, it has a relatively low turnover number or k_{cat}, where k_{cat} is the maximum number of substrate molecules (JH) converted to product (JH acid) per active site per unit time. These factors make the enzyme a very effective scavenger that can "find" JH at physiological concentrations and convert it to JH acid (Abdel-Aal and Hammock, 1986).

Substrate specificity of JHE represents another characteristic that seems counterintuitive. The K_m and V_{max} that the JHEs display towards the JH homologs is surprisingly low when compared to other substrates, such as α-naphthyl acetate. For example, recombinant *M. sexta* JHE displays a K_m (410 μM) and V_{max} (21 μmol min^{-1} mg protein^{-1}) for α-naphthyl acetate that is considerably higher than for its natural substrate, JH III (K_m = 0.052 μM, V_{max} = 1.4 μmol min^{-1} mg protein^{-1}) (Hinton and Hammock, 2003). As noted by Fersht (1985), when specificity is used to discriminate between two competing compounds, it should be determined by the k_{cat}/K_m ratios, and not K_m alone. The k_{cat}/K_m ratio for JH III and α-naphthyl acetate are 27 and 0.04, respectively, underscoring the high degree of specificity of JHE for JH III (Hinton and Hammock, 2003). While these kinetic parameters suggest that the enzyme has a high degree of specificity, it appears that JHEs from several species also hydrolyze methyl and ethyl esters of JH I and III at very similar rates (Grieneisen *et al.*, 1997). Moreover, even *n*-propyl and *n*-butyl esters of these homologs can serve effectively as substrates, albeit at a lower rate of hydrolysis. As might be expected, the unnatural (2*Z*,6*E*)-JH I ethyl ester isomer is not metabolized by JHEs from *M. sexta* or *H. virescens*.

Since hJHBPs have a significant effect on substrate availability (Peter *et al.*, 1979; Peter, 1990; King and Tobe, 1993), studies on JHE specificity must be performed with relatively pure preparations of the enzyme. In those few studies using highly purified or recombinant *T. ni* JHE, it was determined that the JHE hydrolyzed JH I more rapidly than JH II or III and that it displayed a faster catalytic rate for the naturally occurring enantiomer, (10*R*,11*S*)-JH II, than for the (10*S*,11*R*)-JH II form (Hanzlik and Hammock, 1987). However, a comparison of the k_{cat}/K_m ratios for the enantiomers indicated that hydrolysis of the two forms was equivalent (Hanzlik and Hammock, 1987). The same holds true for the gypsy moth, *Lymantria dispar*, in which the JHE shows no enantiomeric selectivity and appears unable to discriminate between

homologs (Valaitis, 1991). One of the most unexpected groups of JHE substrates is found in the naphthyl and *p*-nitrophenyl series. While it was originally concluded that hemolymph JHE from some species, such as *M. sexta*, could not use α-naphthyl acetate as a substrate (Coudron, 1981), the JHEs of other species can recognize members of the naphthyl series (Rudnicka and Kochman, 1984; Hanzlik and Hammock, 1987). More recently it was demonstrated that recombinant JHE from *M. sexta*, *H. virescens*, and *T. molitor* can hydrolyze naphthyl compounds with chain derivatives eight carbons long, thus dispelling the long-held belief that JHE from *M. sexta* is unable to use naphthyl derivatives as substrates (Kamita *et al.*, 2003).

Another counterintuitive observation is that while the major role of JHE is the conversion of JH to JH acid, both native and recombinant JHEs from several species can, under the appropriate conditions, transesterify JH to form the higher ester homologs, i.e., JH ethyl, JH *n*-propyl, and JH *n*-butyl esters (Grieneisen *et al.*, 1997). Although JHE-mediated JH transesterification may be a curiosity limited to the test tube, Debernard *et al.* (1995) demonstrated that when JH III, dissolved in ethanol (10 μl), was injected into *L. migratoria*, it was both converted to JH III acid and transesterified to the JH III ethyl ester. With regard to this particular study, it should be noted that care must be taken to avoid artifacts when alcohols are used as carrier solvents for the hormone in JHE assays. Nevertheless, while JHE in a biological milieu clearly serves as an esterase, these new findings imply that the enzyme may have other physiological roles (see Anspaugh *et al.* (1995) for other possible roles for JHE).

3.7.9.1.3. Protein structure and catalytic site While the catalytic action of JHE is probably similar to that of other esterases, there is some uncertainty about the molecular mechanism by which it operates and some question as to how it can effectively hydrolyze a chemically stable conjugated ester (Hinton and Hammock, 2003). A putative three-dimensional structure of the JHE of *H. zea* has been generated using homology modeling, a structure-building process that uses computer algorithms, based on the assumption that proteins with homologous sequences have similar three-dimensional structures (Thomas *et al.*, 1999). Using the structures of two well-defined carboxylesterases (sequence identity ~28%) as models, these investigators demonstrated that JHE belongs to the α/β hydrolase fold family. The *H. zea* JHE (GenBank Accession no AF037196) possesses a putative catalytic triad of amino acids, including the nucleophilic Ser224, as part of the characteristic motif, G-X-S-X-G (X represents any amino acid residue). The second and third components to the triad are a base, His465, which is part of the G-X-X-H-X-X-D/E motif , and an acid, Glu353, that lie in a deep cleft of approximately 23 Å. The importance of these residues to JH catalysis was confirmed through site-directed mutagenesis (Ward *et al.*, 1992). In addition to the catalytic site, the cleft is lined with a number of hydrophobic amino acids, a situation that might be expected, considering the hydrophobic nature of JH.

One might reasonably expect the catalytic site of JHEs of other species to show some sequence similarity and, not surprisingly, they do. A comparison of sequences among the known lepidopteran JHEs, those of *B. mori* (Hirai *et al.*, 2002), *Choristoneura fumiferana* (Feng *et al.*, 1999), *H. virescens* (Hanzlik *et al.*, 1989), and *M. sexta*, (Hinton and Hammock, 2001), reveals better than 30% identity. The residues associated with the catalytic site are in complete agreement and display the appropriate alignment. Even in species outside the order, such as *D. melanogaster* (Campbell *et al.*, 1992) and *T. molitor* (Hinton and Hammock, 2003), the catalytic sites align with those in Lepidoptera (Feng *et al.*, 1999; Kamita *et al.*, 2003). The only species that does not show alignment of the putative catalytic site is *L. decemlineata* (Vermunt *et al.*, 1997b), which is surprising given the consensus displayed by another beetle, *T. molitor.* With the exception the putative catalytic site residues and a sequence surrounding Ser224, the JHEs as a family are not highly conserved. This might be expected, however, since only the cleft into which the substrate fits needs to be lined with hydrophobic residues (Kamita *et al.*, 2003).

3.7.9.1.4. Juvenile hormone esterase inhibitors The development of effective JHE inhibitors has been an ongoing process since the first studies more than 25 years ago. While JHE inhibitors have yet not been commercialized for agricultural use, they have, nevertheless, been important tools in the discovery of the role of JH catabolism *in vivo*. Two important series of JHE inhibitors have emerged from these studies, the trifluoromethyl ketones (TFKs) and the phosphoramidothiolates (Roe and Venkatesh, 1990). The TFKs, such as 1,1,1-trifluorotetradecan-2-one (TFT), were initially suspected to act as transitional state analogs, mimicking the α,β saturation of JH (Hammock *et al.*, 1982) (**Figure 15**). The transitional state, where the enzyme and substrate form a complex, represents a transitory period in which the chemical bonds of the substrate

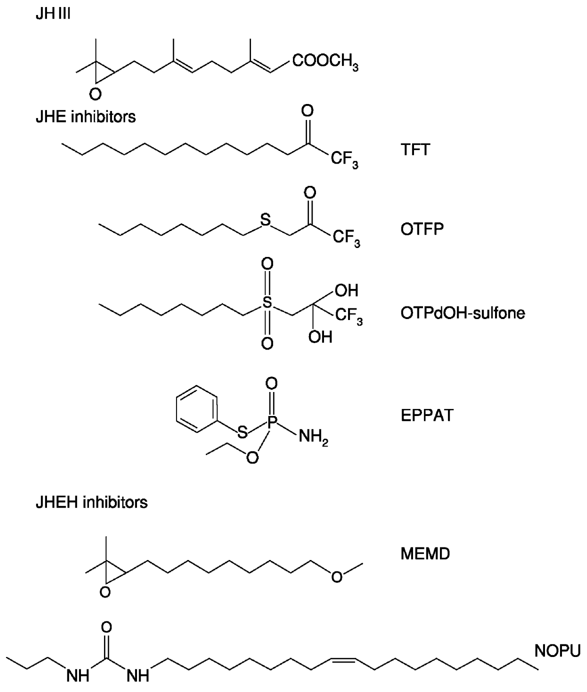

Figure 15 Chemical structures of JH III, JH esterase and JH epoxide hydrolase inhibitors. TFT, 1,1,1-trifluorotetradecan-2-one; OTFP, 3-octylthio-1,1,1-trifluoro-2-propanone; OTPdOH-sulfone, 1-octyl[1-(3,3,3-trifluoropropan-2,2-hydroxy)] sulfone; EPPAT, *O*-ethyl *S*-phenyl phosphoramidothiolate; MEMD, methyl 10,11-epoxy-11-methyldodecanoate; NOPU, *N*-[(*Z*)-9-octadecenyl]-*N*′-propyl urea.

are in the process of being broken and made. Thus, a transitional state analog has the properties of the unstable intermediate. In the catalytic site, the electron-withdrawing inhibitor increases the electrophilicity of the carbonyl group, enhancing its susceptibility to nucleophilic attack by the reactive serine (Hammock *et al.*, 1982). While it was thought that mimicking the JH backbone was important to recognition, further modifications of TFT to resemble JH structure did not improve JHE inhibition. However, introducing a thioether beta to the carbonyl 3-octylthio-1,1,1-trifluoro-2-propanone (OTFP) (**Figure 15**) increased the potency of inhibition at least 100-fold (Abdel-Aal and Hammock, 1985). More recently, it has been demonstrated that 1-octyl[1-(3,3,3-trifluoropropan-2,2-dihydroxy)] sulfone (OTPdOH-sulfone) is a better inhibitor of JHE than OTFP (Roe *et al.*, 1997). The increased inhibition displayed by OTFP-sulfone stems from the increased hydration (Roe *et al.*, 1997; Wheelock *et al.*, 2001). The attractiveness of the TFK-containing inhibitors lies in their reversible binding of the enzyme, which permits their use in affinity-matrix purification of JHEs. Moreover, the TFKs are useful for *in vivo* studies since they are highly specific and appear to have little effect on nonspecific esterases (Roe *et al.*, 1997).

In contrast to the TFKs, the organophosphate inhibitors of JHE, most importantly *O*-ethyl *S*-phenyl phosphoramidothiolate (EPPAT) (**Figure 15**), bind irreversibly to JHE (Hammock, 1985). Like the TFKs, EPPAT appears to be highly selective for JHE and can be used *in vivo*. While EPPAT is only a moderately effective inhibitor of JHE, it has a much longer life *in vitro* than the TFKs.

3.7.9.1.5. Genomic structures At the present time, the genomic structures of only two *JHE*s are completely known, those of *H. virescens* (GenBank Accession no. J04955) (Hanzlik *et al.*, 1989; Harshman *et al.*, 1994) and *D. melanogaster* (GenBank Accession no. AF304352) (Campbell *et al.*, 2001). The *JHE* locus of *H. virescens* is 8 kb in length and is composed of five exons that give rise to an open reading frame of 1.8 kb (Harshman *et al.*, 1994). Unfortunately, nothing is known about the 5′ upstream region in this gene, although the core promoter region for *JHE* has been elucidated in another noctuid, *T. ni* (Jones *et al.*, 1998). In *D. melanogaster,* the *JHE* is localized on the second chromosome and covers approximately 2.5 kb in region 52F1-2 (FlyBase). The gene is composed of five exons (note: Flybase incorrectly indicates six exons) that contain an open reading frame of 1.7 kb. In the 5′ position immediately adjacent to the *JHE* gene is another carboxylesterase gene (Flybase CG 8424) that displays 42% identity with *JHE* and contains the putative catalytic sites (Kamita *et al.*, 2003). This gene is nearly identical in length and is suggested to be a gene duplication (Campbell *et al.*, 2001). Just downstream from *JHE* is the gene *spin,* which is reported to be implicated in female behavior (FlyBase CG8428). Since gene expression may be coordinately regulated by domain control elements (Spitz *et al.*, 2003), a knowledge of neighboring genes may provide new insights into the regulation of *JHE* and potential molecular cascades in which the gene is involved.

3.7.9.1.6. Regulation The importance of JHE in regulating JH titers has prompted a number of investigators to examine its physiological and genetic regulation (review: Gilbert *et al.*, 2000). The primary site of synthesis for the hemolymph JHEs, the fat body (Whitmore *et al.*, 1974; Hammock *et al.*, 1975; Wing *et al.*, 1981), has been the primary focus of many studies that have been reviewed previously in some detail (Roe and Venkatesh, 1990; Roe *et al.*, 1993; deKort and Granger, 1996; Gilbert *et al.*, 2000). Tissues other than the fat body can also

express the enzyme (see Roe and Venkatesh, 1990 for a review of the different tissues; Feng *et al.*, 1999). Even the CA have been found to have JHE activity in a number of species (Sparagana *et al.*, 1984; Wisniewski *et al.*, 1986; Meyer and Lanzrein, 1989a, 1989b), and in one case, the glands secrete measurable, and developmentally fluctuating, amounts of the enzyme into incubation medium (Sparks *et al.*, 1989; Janzen *et al.*, 1991). Most studies conclude that the JHEs of different tissues and at different developmental time points are similar, if not identical, to the hemolymph form of JHE; however, their regulation may be different (Jesudason *et al.*, 1992). Sparks *et al.* (1989) made the novel suggestion that the multiple isoforms of hemolymph JHE may be the result of its production and release into the hemolymph from a variety of tissues.

To best understand JHE regulation, a brief description of hemolymph JHE levels is in order. In *M. sexta*, a peak in hemolymph JHE is observed prior to ecdysis in larval stadia two through five (Roe and Venkatesh, 1990), with activity in each stadium increasing in direct proportion to larval weight (Roe *et al.*, 1993). Although levels of JHE activity during the earlier stadia are lower, the precise timing and appearance of JHE and its developmental profile in relation to total hemolymph protein suggests specific regulation. However, the role of the JHE in the early instars is unclear, since hemolymph JH titers remain relatively high even in the presence of enzyme (Hidayat and Goodman, 1994).

In contrast to the earlier stadia, the developmental profiles of JHE activity and of JH titers during the last stadium of *M. sexta* reveal two peaks (Vince and Gilbert, 1977; Baker *et al.*, 1987; Roe and Venkatesh, 1990). Titers of JH are highest in the hours immediately following the molt from the fourth to the fifth stadium (**Figure 16**). They then drop dramatically, becoming undetectable by 48 h after ecdysis. JH titers rise a second time to peak at 156 h and then decline prior to metamorphosis. JHE activity begins to climb midway through the feeding period and peaks shortly before wandering. A smaller rise in JHE activity appears after the second peak of JH but drops at pupation (Baker *et al.*, 1987). Similar developmental profiles are seen in the last stadium of *S. littoralis* (Zimowska *et al.*, 1989) and *L. decemlineata* (deKort, 1990). Most studies have pinpointed the fat body as the primary source of JHE in the hemolymph (Wing *et al.*, 1981; Wroblewski *et al.*, 1990). However, Jesudason *et al.* (1992) suggest that the first peak of JHE, which occurs during the feeding stage, is of fat body origin, while the second peak, during the prepupal phase, is not. Alternatively, it could be that in this study, the preparation of prepupal fat body samples in the absence of protease inhibitors led to the destruction of JHE at this stage. While the JHE profile in hemolymph appears to be similar for most lepidopterans, it appears to differ outside of this order: some species have a single burst of JHE activity that declines either midway through the last stadium or at the very end of larval life (review: Roe and Venkatesh, 1990).

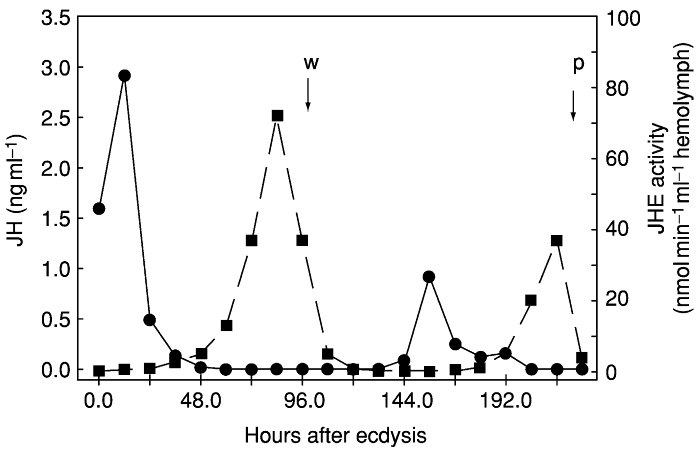

Figure 16 Hemolymph JH titer and JHE activity during the fifth stadium of *M. sexta* larval development. Closed circles, total titer for all homologs detected (JH 0, I, II, III). JH acids are not included. JH titers were combined for both females and males and expressed as the average. Closed squares, JHE activity. JHE activities were combined for both females and males and expressed as the average. W, onset of wandering behavior; P, time of pupal ecdysis. (Adapted from Baker, F.C., Tsai, L.W., Reuter, C.C., Schooley, D.A., **1987**. *In vivo* fluctuation of JH, JH acid, and ecdysteroid titer, and JH esterase activity, during development of fifth stadium *Manduca sexta*. *Insect Biochem.* *17*, 989–996.)

As can be seen in **Figure 16**, the rise in JHE activity after the JH titer drops does not support the concept that the enzyme is directly responsible for the decline in JH titers. Nevertheless, the enzyme displays exceptional scavenging properties, and it may be that the increase in enzyme activity occurs to ensure that no detectable JH is present during commitment to pupation. More problematic is the observation that JH is not totally eliminated when JHE is present. For example, a comparison of JH levels in the penultimate stadium of *M. sexta* (Hidayat and Goodman, 1994) with JHE levels during this same period (Roe and Venkatesh, 1990) reveals measurable JH in the presence of JHE. The results of similar studies of the fifth stadium in this species strongly suggest that the pre-wandering peak of JHE has no functional relationship to metamorphosis (Browder *et al*., 2001). While not stated explicitly, the same conclusion can be drawn from studies in *T. ni* (Sparks *et al*., 1979; Hanzlik and Hammock, 1988; Jones *et al*., 1990b), and in still another case, JH levels appear refractory to JHE in diapausing larvae of the European cornborer, *Ostrinia nubilalis* (Bean *et al*., 1982). Although hemolymph JHE levels follow a developmental pattern that suggests the enzyme may be directly involved in JH catabolism, there remains a degree of uncertainty about the assumed role of JHE in eliminating the hormone from the circulatory system.

That JHE levels do not follow a developmental pattern typical of other hemolymph proteins prompted a search for possible regulatory mechanisms modulating its activity. A logical candidate for JHE regulation is JH itself, but regulation of JHE by JH in lepidopteran larvae, especially during the last larval stadium, depends on whether the insect is in the pre-wandering or post-wandering phase. In the pre-wandering phase of the last larval stadium, JH regulation of hemolymph JHE levels is ambiguous. The brain appears to play an inhibitory role in control of JHE activity, and there are other factors, such as tissue competence, that seem to be involved as well (Venkatesh and Roe, 1988; Jesudason *et al*., 1992; Roe *et al*., 1993). In contrast, manipulation of JH titers by surgical and chemical means during the post-wandering period of the last stadium has a direct impact on JHE activity (Roe *et al*., 1993; review: Gilbert *et al*., 2000). Treatment of larvae with JH or JH analogs leads to an increase in JHE activity in the hemolymph, while allatectomy leads to a decline in JHE that can be reversed by supplying exogenous hormone. At the molecular level, nuclear run-on experiments using the fat body of *T. ni* have confirmed that exogenous JH or JH analogs stimulate *JHE* expression and that the response can be detected within 3 h of treatment (Venkataraman *et al*., 1994). Using a cell line derived from the midgut of *C. fumiferana,* Feng *et al*. (1999) demonstrated that JH can increase the abundance of JHE mRNA within 1 h, suggesting a potential upregulation of *JHE* expression by JH. However, these investigators rightfully caution that the apparent rise in message could also be due to stabilization of JHE mRNA. Curiously, the potent protein synthesis inhibitor, cyclohexamide, mimicked the action of JH, prompting the suggestion that an inhibition of protein synthesis leads to an increase in the accumulation of JHE message or, alternatively, stabilization of the message. In contrast to the apparent stimulation of expression levels by JH, the presence of 20E in the medium leads to a decrease in JHE mRNA, in a dose-dependent manner (Feng *et al*., 1999). This discovery indicates that regulation of *JHE* expression is more complex than first thought and that ecdysteroids must be considered in the overall regulatory system.

The endocrine system is an important bridge between the target cell and the environment, and it is axiomatic that environmental factors are major players in regulation of the endocrine system. Factors such as stress (Gruntenko *et al*., 2000), circadian cues that induce diapause (Bean *et al*., 1982, 1983), nutrition (Cymborowski *et al*., 1982; Sparks *et al*., 1983; Venkatesh and Roe, 1988; Roe and Venkatesh, 1990), and parasitism (Hayakawa, 1990; see Edwards *et al*., 2001 and references therein) are all thought to play a role in regulating JHE levels and are undoubtedly transduced by the nervous system.

3.7.9.1.7. Catabolism of juvenile hormone esterase

After a rapid increase midway through the feeding period of the last stadium in Lepidoptera, JHE levels drop dramatically immediately prior to the onset of wandering. Experimental evidence corroborates this observation: the half-life of recombinant JHE when injected into second instars of *M. sexta* is approximately 20 min, while other exogenously supplied proteins of similar molecular mass display half-lives measured in days (Ichinose *et al*., 1992). Since no cleavage products of JHE can be detected in the hemolymph, Ichinose *et al*. (1992) suggested that the enzyme is removed from the circulatory system by cellular uptake. It was discovered that the pericardial cells were responsible for uptake and destruction of the hemolymph JHE (Ichinose *et al*., 1992). Pericardial cells are a collection of cells that surround the insect heart in various configurations, depending upon the order (Wigglesworth, 1972; Crossley, 1985). In *M. sexta,*

the pericardial mass is punctuated with numerous labyrinthine channels that increase exposure of the cells to the hemolymph (Brockhouse *et al.*, 1999), and it is thought that this tissue mass is responsible for the removal of hemolymph proteins and small colloidal particles from the hemolymph (Crossley, 1985).

It is speculated that the rapid removal of JHE from the hemolymph by the pericadial cells occurs via receptor-mediated endocytosis, followed by transport to lysosomes for destruction (Bonning *et al.*, 1997). During the passage from the endosome to the lysosome, JHE interacts with putative heat shock cognate proteins with relative molecular masses of 100 and 140 kDa. These pericardial cell-specific proteins cross-react with a universal antiserum directed towards heat shock protein 70, hence the designation as cognate (Shanmugavelu *et al.*, 2000). In addition to the heat shock proteins, a novel 29 kDa protein, termed P29, appears to bind and target JHE for lysosomal destruction. This protein has been detected in fat body and pericardial cells of insects from all five larval stadia in *M. sexta*. The P29 gene has been identified using a phage display library and has been sequenced (GenBank Accession no. AF233526).

3.7.9.2. Juvenile Hormone Epoxide Hydrolases

The preponderance of literature on JH catabolism has focused on the role of JHE in metamorphosis, yet the less well-studied pathway, i.e., epoxide hydration via JH epoxide hydrolase (JHEH), may actually be more biologically relevant in some species (Gilbert *et al.*, 2000). For example, when JH I is injected into early fifth instars of *M. sexta*, the major metabolite is not JH acid or JH acid-diol, but a JH diol phosphate conjugate (Halarnkar *et al.*, 1993). Further evidence that JHEH plays a significant role in the reduction of JH titers at critical times can be found in the mosquito *Culex quinquefasciatus*, in which JHEH activity is two to four times higher than JHE activity throughout most of the life cycle (Lassiter *et al.*, 1994). Moreover, two peaks of JHEH are seen during the last stadium, suggesting that the enzyme is involved in JH metabolism during critical developmental periods (Lassiter *et al.*, 1995). Even in *T. ni*, with which so many of the JHE studies have been done, JH diol is a major metabolite or intermediate (Kallapur *et al.*, 1996). It appears that the contribution of JHEH to the overall catabolism of JH varies extensively, even within the same order (Hammock, 1985).

3.7.9.2.1. Physical properties The JHEHs (EC.3.3.2.3) belong to a large family of proteins that display the αβ hydroxylase fold (Debernard *et al.*, 1998) and they are responsible for hydration of the JH epoxide to a diol. Since hydrolases are involved in a wide range of enzymatic reactions and utilize multiple substrates, it has been justifiably cautioned that JHEHs may not be as specific as they are portrayed (Harris *et al.*, 1999). Nevertheless, the term JHEH will be employed as it is commonly used in the literature.

A number of species have been catalogued as having JHEH activity (Hammock, 1985), but in only a few species have the JHEHs been well characterized. Because a single species may have more than one form of JHEH (Harshman *et al.*, 1991; Keiser *et al.*, 2002), it has been suggested that the different JHEHs represent tissue-specific enzymes (Harshman *et al.*, 1991). Epoxide hydrolases are present in both soluble (cytoplasmic) and insoluble (microsomal) forms, but the EHs responsible for hydration of the epoxide are found associated mainly with the microsomal fraction (Wisniewski *et al.*, 1986; Touhara and Prestwich, 1993; Wojtasek and Prestwich, 1996; Harris *et al.*, 1999; Keiser *et al.*, 2002). JHEH appears to be a monomer, with a relative molecular mass ranging from 46 to 53 kDa (Harshman *et al.*, 1991; Touhara and Prestwich, 1993; Harris *et al.*, 1999; Keiser *et al.*, 2002). In general, the pH range for JHEH activity is broad, extending from approximately pH 5 to 9, probably reflecting the involvement of the reactive histidine (pK_a 6.5 for the imidazole group) in the catalytic site (Debernard *et al.*, 1998). The JHEHs of *D. melanogaster* are heat- and organic solvent-tolerant, withstanding incubation at 55 °C and concentrations of ethanol exceeding 40% (Harshman *et al.*, 1991). Moreover, the recombinant enzyme from *M. sexta* retains full activity in the presence of low levels of the reducing agent dithiothreitol and a sulphydryl modifying reagent, iodoacetamide (Debernard *et al.*, 1998).

3.7.9.2.2. Kinetic parameters, specificity, and the catalytic site Determinations of the kinetic parameters of the JHEH from the microsomal fraction of *M. sexta* eggs revealed K_m values for JH I, II, and III of 0.61, 0.55, and 0.28 μM, respectively (Touhara and Prestwich, 1993). Interestingly, the V_{max}:K_m ratio for JH III, the least abundant egg homolog (Bergot *et al.*, 1981a), was 25 times greater than that for JH I, suggesting that the enzyme displays considerably more specificity for JH III than the higher homologs (Touhara and Prestwich, 1993). This observation was confirmed by Debernard *et al.* (1998), using recombinant JHEH from *M. sexta*; while the enzyme could hydrolyze

JH I, II, and several synthetic substrates, JH III was the most favored substrate. JH III is also a better substrate for JHEH than JH acid (Touhara and Prestwich, 1993; Kallapur *et al.*, 1996), and in *D. melanogaster*, JH III is a more suitable substrate than JHB_3 (Casas *et al.*, 1991). If JH III is the optimal substrate for JHEH, then JHEH may indeed be the enzyme responsible for intracellular JH catabolism, especially since with the exception of JHB_3, JH III is the only or predominant JH in all insect orders but Lepidoptera (see Section 3.7.2.1). However, as noted by Harris *et al.* (1999), more direct evidence, such as a correlation between inhibition of the enzyme *in vivo* and a decrease in JH metabolism, is required before assuming the enzyme is JH III-specific.

As noted by several groups, the high degree of conservation of the catalytic site suggests that the mechanism of epoxide hydration is similar to that found in mammals (Roe *et al.*, 1996; Wojtasek and Prestwich, 1996; Debernard *et al.*, 1998). Using the JHEH of *M. sexta* as a model, Debernard *et al.* (1998) proposed a two-step catalytic process. The first step involves a nucleophilic attack of the epoxide at the least hindered position, C10, by Asp227. This, in turn, opens the ring, leading to the formation of an hydroxyl-alkyl enzyme. The neighboring Trp228 is thought to activate the epoxide for a nucleophilic attack (Harris *et al.*, 1999). The second step involves the hydrolysis of this covalent intermediate by a water molecule that is activated by His428 and Asp350. The histidine residue activates water with an Asp or Glu residue acting as the proton scavenger from the histidine to reactivate the enzyme. The resulting product is (10*S*,11*S*)-JH diol. A variation on this putative reactive site was found by Linderman *et al.* (2000), in which the site uses Glu403 instead of Asp350 as the charge relay partner with the histidine residue. There is remarkable sequence conservation of the catalytic triad and its surrounding residues among both insects and mammals. All JHEHs, like their mammalian counterparts, contain a tryptophan residue at positions 150–155, forming part of the oxyanion hole that may stabilize the hydroxyl-alkyl intermediate (Lacourciere and Armstrong, 1993; Wojtasek and Prestwich, 1996; Keiser *et al.*, 2002).

3.7.9.2.3. Juvenile hormone epoxide hydrolase inhibitors In contrast to the early and successful discoveries of highly effective JHE inhibitors, the search for JHEH inhibitors has been less productive until recently (Hammock, 1985; Casas *et al.*, 1991; Harshman *et al.*, 1991; Roe *et al.*, 1996). Investigations have taken one of two directions, examining either compounds that mimic the JH backbone (Roe *et al.*, 1996; Linderman *et al.*, 2000) or compounds based on urea and amide pharmacophores that are not subject to metabolism through epoxide degradation (Severson *et al.*, 2002).

Roe *et al.* (1996) demonstrated that methyl 10,11-epoxy-11-methyldodecanoate (MEMD), a long-chain aliphatic epoxide (**Figure 15**) displays an I_{50} (molar concentration needed to inhibit 50% of enzyme activity) in the low nanomolar range. A promising group of MEMD analogs was investigated by Linderman *et al.* (2000), who re-examined the structure–activity relationship of MEMD epoxide substitution and enantioselectivity. Two classes of MEMD analogs were synthesized, a glycidol-ester series and an epoxy-ester series. As a group, the glycidol-esters were more potent inhibitors than the corresponding epoxy-esters, by an order of magnitude. The inhibitory activity in both classes was found to be dependent upon the absolute configuration of the epoxide at C10, with the *R* configuration displaying the higher degree of inhibition. The inhibitory activity of the most potent compound of the series ($I_{50} = 1.2 \times 10^{-8}$ M) is thought to be due to the hydroxyl group in the active site, which forms an additional hydrogen bond. This bond may stabilize the enzyme–inhibitor complex by inducing a conformational change, or it could reduce the rate at which the diol product dissociates from the enzyme's active site.

The other class of JHEH inhibitors is the analogs of the ureas and amide pharmacophores that have been demonstrated to be potent inhibitors of mammalian soluble and microsomal epoxide hydrolases in mammals (Severson *et al.*, 2002). To date, none of the nearly 60 compounds tested are as active as the glycidol-esters in the inhibition of recombinant *M. sexta* JHEH (**Figure 15**), a surprising result, given their action on mammalian enzymes. The most potent of the series, *N*-[(*Z*)-9-octadecenyl]-*N*′-propyl urea (NOPU), has an $I_{50} = 8.0 \times 10^{-8}$ M. Severson *et al.* (2002) suggest that when the inhibitor enters the catalytic site, the carbonyl group of the urea interacts with two tyrosine residues in the oxyanion hole. Since the inhibitor lacks an epoxide, it does not covalently bind to the reactive Asp227 residue, but it does block the catalytic site from further activity.

3.7.9.2.4. Genomic structures At the present time, the genomic structure of only one insect *JHEH* gene is known, that of *D. melanogaster*. The gene cluster, approximately 8.6 kb, is located on chromosome 2 in region 55F7-8, near the *JHE* locus at 52F1. As suggested by Harshman *et al.* (1991) and confirmed

through genomic studies (FlyBase), there are multiple forms of *JHEH* in *D. melanogaster.* Annotation of the *JHEH* locus identifies three putative genes that display approximately 37% identity in their amino acid sequence. The genomic region containing *JHEH1* (GenBank Accession no. NM_137541; CG15101) is approximately 1.8 kb and contains four exons. Approximately 0.7 kb downstream from *JHEH1* lies *JHEH2* (GenBank Accession no. NM_137542; CG15102), which is 2.2 kb in length and has two potential transcripts. One transcript has four exons (GenBank Accession no. NM_137524; CG15102) while the other has three (GenBank Accession no. NM_176233; CG15102). At 0.3 kb downstream from *JHEH2* lies the gene *Bari* which encodes a transposable element. *JHEH3* (GenBank Accession no. NM_137543; CG15106) lies about 0.3 kb downstream from the transposable element and is composed of three exons. No genes of obvious relation to JH action or catabolism lie close to the *JHEH* locus. *JHEH1* and *2* are more related to each other than to *JHEH3*; all three putative genes display the residues of the catalytic triad in the correct sequence, and all are of about the same length. Computational analysis using CLUSTALW indicates that *JHEH1* and *3* are most divergent in their first 70 residues, which might be expected if the *N*-terminal is needed for attachment to cell membranes. Since JHEH activity has been demonstrated in other cell fractions besides microsomes (Casas *et al.*, 1991; Harshman *et al.*, 1991), it may well be that the first exons of *JHEH1* and *3* code for sequences that target these enzymes for different locations within the cell.

Recent evidence suggests that the N-terminal of EHs may play another role. The soluble human EH, EPXH2, also possesses phosphatase activity, so the enzyme can not only transform epoxy fatty acids to their corresponding diols but also dephosphorylate dihydroxy lipid phosphates (Newman *et al.*, 2003). The phosphatase activity localized to the *N*-terminal domain is unaffected by a number of classic phosphatase inhibitors. Alignment of EPXH2 with several of the insect JHEHs shows less than 25% amino acid sequence similarity under nonstringent conditions, and regions of similarity are limited to the C-terminal domain. Nevertheless, the possibility of an insect JHEH with phosphatase activity presents an interesting twist in the metabolic pathway for JH catabolism (see Section 3.7.9.3).

3.7.9.3. Secondary Metabolism of Juvenile Hormone: Juvenile Hormone Diol Kinase

Secondary metabolism of JH has been examined in a number of investigations (Roe and Venkatesh, 1990; Halarnkar *et al.*, 1993; Grieneisen *et al.*, 1995), but as noted by Halarnkar *et al.* (1993), the results of these studies may be misleading, since the enzymes used may have contained multiple hydrolytic activities. In only one instance has an actual JH conjugate been unequivocally identified. The conjugate, (10*S*,11*S*)-JH diol phosphate (**Figure 1**), is the product of a two-step enzymatic process: conversion of JH to JH diol and then addition of a phosphate group to C10 (Halarnkar *et al.*, 1993). The enzyme responsible for the phosphorylation of JH diol is JH diol kinase (JHDK), which has been characterized from the Malpighian tubules of early fifth instars of *M. sexta* (Grieneisen *et al.*, 1995; Maxwell *et al.*, 2002a, 2000b). The discovery of JHDK (EC 2.1.7.3) was made when an analysis of JH I metabolites *in vivo* yielded, in addition to JH diol and JH acid, a very polar JH I conjugate that was subsequently identified as JH I diol phosphate (Halarnkar and Schooley, 1990).

3.7.9.3.1. Physical properties JHDK from *M. sexta* Malpighian tubules is a cytosolic protein composed of two identical subunits of 20 kDa, as determined by mass spectrometry (Maxwell *et al.*, 2002a). Gel filtration studies indicate it has a molecular mass of approximately 43 kDa, and it has been suggested that the native form of the enzyme is homodimeric. JHDK displays a K_m in the nanomolar range for JH I diol, which is appropriate for an enzyme responsible for clearance of a hormone whose titers rarely exceeds 10 nM. Most significantly, the developmental profile of catalytic activity for JHDK parallels that for JHEH, a requisite if JH diol phosphate is a legitimate terminal metabolite. Analysis of the k_{cat}/K_m parameter for the diols of JH I, II, and III indicates that JH I diol is the preferred substrate, suggesting a preference for an ethyl group at the C7 position. JHDK requires both Mg^{2+} and ATP for activity (Grieneisen *et al.*, 1995; Maxwell *et al.*, 2002a), although excess Mg^{2+} or Ca^{2+} inhibits its activity (Maxwell *et al.*, 2002a). When stored in the appropriate buffers, the enzyme is reasonably stable but it is very sensitive to various metal ions.

The specificity of JHDK for JH I diol is relatively high, considering the multitude of potential phosphate acceptor groups present in a cell. The enzyme does not recognize methyl geranoate diol (one isoprenyl unit shorter than JH) nor methyl geranylgeranoate diol (one isoprenyl group longer than JH), yet it does recognize JH I ethyl ester diol. It also recognizes both JH diol enantiomers, indicating that absolute stereospecificity of the hydroxyl groups is of minor importance.

Most surprising is the enzyme's inability to recognize JH acid diols. If JH acid diol cannot be phosphorylated by JHDK, the fact that JH diol phosphate is a significant metabolite (Halarnkar *et al.*, 1993) must be explained otherwise. JH acid diol could undergo further catabolism by cytochrome P-450s (Sutherland *et al.*, 1998). However, the role of cellular JHE becomes problematic if the pathway catalyzed by JHEH and JHDK is the major pathway for JH catabolism in the cell. There may yet be undiscovered enzymes in cellular JH catabolism.

3.7.9.3.2. Genomic structures The sequence and hypothetical structure of the *M. sexta* and *D. melanogaster JHDK* genes have recently been examined by Maxwell *et al.* (2002b). A partial characterization of JHDK from whole body homogenates of *D. melanogaster* indicates that it is similar to the enzyme in *M. sexta*, with the exception of its subunit structure. The active *D. melanogaster* JHDK is composed of a single monomer of ~20 kDa, while the active *M. sexta* JHDK is composed of two identical 20 kDa subunits. This latter gene (GenBank Accession no. AJ430670) has been sequenced and found to code for an enzyme that has 59% sequence identity and >80% similarity to sarcoplasmic calcium-binding protein 2 (dSCP2) of *D. melanogaster* (GenBank Accession no. AF093240; CG14904). Similarities in chromatographic properties, isoelectric point, and enzyme activity led Maxwell *et al.* (2002b) to conclude that dSCP2 is the probable *D. melanogaster* homolog of *M. sexta* JHDK.

Maxwell *et al.* (2002b) used computer modeling and docking programs to generate a three-dimensional model of JHDK. They capitalized on two facts: (1) the catalytic site of JHDK must contain both a purine binding site (MgATP or MgGTP) and a hydrophobic pocket for JH diol; (2) the scaffolding for another sarcoplasmic calcium-binding protein is known. Both the *M. sexta* and *D. melanogaster* JHDKs contain the three conserved nucleotide-binding elements common to nucleotide binding proteins, surrounding the putative substrate-binding site. The model further demonstrates that the protein contains four domains that form two pairs of a helix–loop–helix motif (EF-hand) (Branden and Tooze, 1999). The model's charge interactions in the hydrophobic binding pocket, as well as its depth (19 Å), are complementary to the extended conformation of the diol. Moreover, the hydrophobic nature of the binding pocket complements the C1 ester of the substrate and supports the observation that JH diol is the only substrate for this enzyme (Maxwell *et al.*, 2002a).

3.7.9.4. Juvenile Hormone Catabolism and New Directions

The field of JH catabolism is changing with the application of sophisticated analytical tools and the use of metabolism studies *in vivo* to uncover potential catabolic pathways. The combination of the two approaches has led to the surprising discovery that JH diol phosphate conjugates are major JH catabolites, thus emphasizing the role of JHEHs in clearing JH from the body (Halarnkar *et al.*, 1993; Gilbert *et al.*, 2000). That discovery has revealed a significant problem in the JHE phase-separation assay. While this assay is a powerful tool, it also detects polar metabolites resulting from enzymatic activity other than that of JHE. In addition, it is critical that the correct controls be employed. This point is driven home by the fact that JHEs from several species can, under the appropriate conditions, transesterify JH (Debernard *et al.*, 1995; Grieneisen *et al.*, 1997). Thus, the JHE phase separation assay should be employed only as the first step in the search for new JH catabolites. The assay should be followed by the use of the advanced chromatographic tools and detection systems now available for identifying trace polar metabolites. The need to demonstrate biological relevance applies not only to the newly discovered JH-like molecules (see Section 3.7.3.1), but also to the enzymes involved in JH catabolism. It may well be that some of the enzymes are really not JH-directed, but will, under experimental conditions, generate metabolites not seen under *in vivo* conditions.

Analysis of JHE activity is further complicated by the existence of both hemolymph and tissue JH binding proteins that preferentially bind certain homologs (Goodman *et al.*, 1976; Park *et al.*, 1993) and enantiomers (Schooley *et al.*, 1978b). These proteins have a significant influence on JHE activity (Hammock *et al.*, 1975) due to preferential binding of one enantiomer (Peter, 1990) or homolog (Halarnkar *et al.*, 1993) over another (see Section 3.7.8.2.1). The recent development of chromatographic methods to separate racemic preparations of JH should alleviate some of these problems (Cusson *et al.*, 1997).

Finally, in the drive to discover a unifying theory to explain JH catabolism, the diversity of the class Insecta is often overlooked. While synthesis of the results of different studies is unavoidable, to assume that all insect species use a single common pathway for JH catabolism would be a gross

oversimplification of the real situation. One need only compare JH metabolism in the flea *Ctenocephalides felis*, which utilizes JHE (Keiser *et al*., 2002), *D. melanogaster*, which utilizes JHEH (Casas *et al*., 1991), and the moth *T. ni*, which utilizes both pathways (Kallapur *et al*., 1996), to understand that multiple pathways for JH catabolism have evolved in this diverse class.

3.7.10. Juvenile Hormones in Embryological Development

The role of JHs in embryonic development remains an enigma despite the discovery of the hormones in the eggs of *H. cecropia* more than 40 years ago (Gilbert and Schneiderman, 1961). However, the paradigm that so elegantly describes the developmental action of JH during larval to pupal metamorphosis has not, until recently, seemed applicable to the embryonic development of insects. The observation that JH titers rise at different times during embryogenesis of hemimetabolous and holometabolous insects has led Truman and Riddiford (1999) to speculate that JH may have played a significant role in the evolutionary divergence of these two groups. As the evidence presented below indicates, the role of JH during embryonic development warrants further consideration.

3.7.10.1. Juvenile Hormone Homologs and Precursors Present during Embryogenesis

The JH homologs from embryos of only a few species have been identified thus far (**Table 1**), giving us a very incomplete picture. What does emerge from these limited data is confirmation that JH III in nonlepidopteran insects is the predominant embryonic hormone, and following the pattern observed in other stages (Schooley *et al*., 1984). Furthermore, JH homologs and precursors not detected in larvae or adults exist in eggs, including JH 0, 4-methyl JH I, and the JH precursor, MF. Even more remarkable are the measurable titers of these homologs and precursors in whole-body extracts of embryos. While it is difficult to compare titers in whole-body extracts with those in hemolymph, the levels of JH in the embryo do appear significantly higher than those in hemolymph at any time during larval development (Edwards *et al*., 2001).

3.7.10.2. Role of Methyl Farnesoate during Embryogenesis

One of the more interesting JH-like molecules found in embryos is MF, the final precursor in the pathway to JH III biosynthesis. While MF possesses the farnesyl backbone of the JHs, it lacks the terminal epoxide at the C10 position (**Figure 1**) and exhibits relatively low activity in bioassays when compared to JH III (Sláma *et al*., 1974). Several investigators have reported high levels of JH III and MF in *N. cinerea* midway through embryonic development (Baker *et al*., 1984; Lanzrein *et al*., 1984; Brüning *et al*., 1985). Using the RCA, Bürgin and Lanzrein (1988) demonstrated that the embryonic CA are indeed synthesizing JH III and MF. The CA of *N. cinerea* become differentiated just before dorsal closure of the embryo, and synthesis of MF and JH III begins shortly thereafter (Bürgin and Lanzrein, 1988). MF levels rise first, followed by JH III about a day later. Both MF and JH III levels remain elevated for several days, exceeding 800 ng g^{-1}, and then decline during the later stages of embryonic development with MF decreasing to undetectable levels (Brüning *et al*., 1985).

Table 1 Juvenile hormone homologs present during insect embryogenesis

Species	*Hormones*	*Reference*
Thermobia domestica	JH III	Baker *et al.* (1984)
Blatella orientalis	JH III	Short and Edwards (1992)
Nauphoeta cinerea	JH III, methyl farnesoate	Baker *et al.* (1984), Brüning *et al.* (1985)
Locusta migratoria	JH III	Temin *et al.* (1986), Pener *et al.* (1986)
Telogryllus commodus	JH III	Loher *et al.* (1983)
Oncopeltus fasciatus	JH III	Bergot *et al.* (1981a)
Leptinotarsa decemlineata	JH III	deKort *et al.* (1982)
Melolontha melolontha	JH III	Trautmann *et al.* (1974)
Heliothis virescens	JH 0, I, II	Bergot *et al.* (1981a)
Spodoptera littoralis	JH I, II, III	Steiner *et al.* (1999)
Manduca sexta	JH 0, I, II, 4-Me JH I	Bergot *et al.* (1981a)
Hyalophora cecropia	JH 0, I, II	Bergot *et al.* (1981a)
Bombyx mori	JH I, II, III	Gharib *et al.* (1983)
Apis mellifera	JH III	Rembold *et al.* (1992)

Recent studies on another cockroach, *D. punctata*, support the hypothesis that MF is a major product of the embryonic CA (Stay *et al.*, 2002). Using the RCA to monitor rates of MF and JH III synthesis, these investigators demonstrated that production of MF increases approximately a day before that of JH III and, as in the case of *N. cinerea*, synthesis of both compounds begin shortly after dorsal closure. Ultrastructural studies of the CA confirm the synthetic activity of the glands after dorsal closure (Lee and Chiang, 1997). In contrast to *N. cinerea*, where MF and JH III are found in equivalent amounts, the biosynthetic rate of JH in *D. punctata* exceeds that of MF by 30-fold.

Stay *et al.* (2002), examining the role of *D. punctata* allatostatin 7 (see Section 3.7.7.2) in regulating MF and JH biosynthesis in *D. punctata* embryos, found the process complex. This potent inhibitor of JH III biosynthesis in adults also inhibits synthesis of MF and JH after dorsal closure. However, prior to dorsal closure, the allatostatin has the reverse effect, stimulating MF biosynthesis. Prior to innervation by neurons transporting the allatostatin, the CA produce MF and can be stimulated by Dippu-AST to produce MF in a dose-dependent manner. Following innervation by Dippu-AST-containing neurons, the glands begin to synthesize both MF and JH, and exogenous Dippu-AST downregulates synthesis of both molecules.

A study with *N. cinerea* embryos is a reminder that MF and JH III cannot be viewed as equivalent or interchangeable (Brüning and Lanzrein, 1987). Treatment of *N. cinerea* embryos with ethoxy-precocene eliminates JH III titers but has little effect on MF levels; yet, the investigators were able to rescue ethoxy-precocene treated embryos with JH III. Interestingly, although ethoxy-precocene is known to induce destruction of the CA in certain insect species, it does not chemically allatectomize this species. Histological studies revealed that as late as 10 days after ethoxy-precocene treatment, the CA were similar to control CA in size and cell number but the nuclei appeared pycnotic. It remains to be seen whether MF is important to embryonic development in *N. cinerea* and *D. punctata*, or in any other species.

3.7.10.3. Juvenile Hormone Titers during Embryogenesis: Correlation with Developmental Events

As noted previously (see Section 3.7.10.1), the action of JH during embryogenesis is unclear and may be different from its role of maintaining the status quo role during the larval stage. Associating changes in JH titers to events in organogenesis could provide clues to the role(s) of JH during embryogenesis. Short and Edwards (1992) measured JH titers in embryos of the cockroach *Blattella orientalis*, and demonstrated that JH III is present at very low levels at oviposition and in the period preceding dorsal closure. Midway through embryogenesis, JH III titers rise dramatically, reaching better than 600 ng g^{-1} of tissue before decreasing. Unfortunately, the investigators did not associate the JH titers with specific embryological events, thus making it difficult to link the peak with any specific developmental process. By contrast, Brüning *et al.* (1985) were able to demonstrate that JH III appears in the embryo of *N. cinerea* only after dorsal closure; no hormone was detected prior to dorsal closure. As in the case of *B. orientalis*, JH III in embryos of *N. cinerea* rises to a very high level (800 ng g^{-1} of tissue). The titer remains high for about 8 days and then falls to undetectable levels prior to emergence.

Temin *et al.* (1986) conducted a closely timed study of JH titers during embryonic development of *L. migratoria*. During the first 60 h after oviposition, JH III levels remain reasonably constant at about 15 pg per egg. Blastokinesis, a movement of the embryo in relation to the yolk mass that consists of two phases (anatrepsis and katatrepsis) (Johannsen and Butt, 1941), occurs from 60 to 108 h after oviposition. During this time, JH is undetectable; however, at dorsal closure, which occurs at approximately 120 h, JH titers begin to rise and reach their highest level at 180 h. Unlike the massive peak in the JH titer observed in *B. orientalis* and *N. cinerea*, the peak titer in *L. migratoria* is approximately 45–50 pg per egg. Levels then fall slowly and are undetectable at the time of nymphal emergence. It is interesting that no JH is detected during the period between the initiation of blastokinesis and dorsal closure, a time that corresponds to the most active period of organogenesis (Temin *et al.*, 1986). However, as noted below, exposure to JH during this period can have profound effects on the development of the embryo and larva.

Dorn (1975), using a bioassay to titer embryonic JH in *Oncopeltus fasciatus*, found that newly oviposited eggs contain low, but detectable, levels of JH. He suggests that the hormone found at oviposition is maternal in origin. The titers remain stable during the first 2 days of embryonic development, but then rise rapidly during the third day. This period in *O. fasciatus* is marked by the completion of CA development and katatrepsis. Levels of JH continue to rise during the fourth day of embryonic development, a period in which final dorsal closure occurs, and peak during the fifth day at levels nearly

15 times that found at oviposition. JH levels drop at the time of hatching.

Titers of JH in the embryos of Lepidoptera present a more confusing picture. Using a bioassay, Gilbert and Schneiderman (1961) were the first to demonstrate that unfertilized eggs of *H. cecropia* contained JH. Bergot *et al.* (1981a) subsequently used GC-MS to detect low levels of JH I at 108 h after fertilization, a period following dorsal closure in this species (Riddiford, 1970). After dorsal closure, JH titers rise to a peak at 156 h (520 pg tissue g^{-1}) and then slowly decline to 50 pg tissue g^{-1} at the time of emergence, approximately 250 h after oviposition.

In *M. sexta* embryos, organogenesis has been extensively studied and correlated to JH titers. JH titers are undetectable by GC-MS prior to provisional dorsal closure (~54 h after oviposition) (Bergot *et al.*, 1981a; Dorn *et al.*, 1987). The titers rise to their highest level between 60 and 72 h after oviposition, when a true larval cuticle appears. Interestingly, this peak in JH is composed of several homologs, including JH 0 and 4-methyl JH I, that are unique to the embryonic stage of Lepidoptera. The titers drop to less than 50 pg g^{-1} total JH at the time of hatching, approximately 120 h after oviposition.

Using an HPLC/bioassay method to measure JH levels in the embryo of the noctuid *T. ni*, Grossniklaus-Bürgin and Lanzrein (1990) showed that JH titers rise during the period of early segmentation, prior to dorsal closure, and remain detectable throughout the period of early organogenesis. As has been observed in other species, the JH titer increases to its highest level shortly after dorsal closure and then declines at hatching. The extensive embryological landmarks available for *T. ni* permit a direct correlation of the peak in the JH titer with the formation of the first larval cuticle.

A similar JH profile is observed in another noctuid, *S. littoralis* (Steiner *et al.*, 1999). GC-MS quantitation was used to demonstrate that low levels of JH II are detectable prior to dorsal closure, during a period in which segmentation and limb growth is extensive. JH titers are at their highest after dorsal closure and more precisely, highest at the time the true larval cuticle is being formed. Titers drop as the embryo develops, but in contrast to other species where the hormone declines to undetectable levels at hatching, *S. littoralis* maintains elevated titers of JH through to emergence.

Despite the extensive body of work concerning JH and caste differentiation in *A. mellifera* (Huang *et al.*, 1991; Schulz *et al.*, 2002) (see **Chapter 3.13**), there is little information linking embryological markers with JH titers in this species. Rembold *et al.* (1992) found that JH III levels are undetectable by GC-MS until very late in embryogenic development (66 h after oviposition). The late peak in the JH titer (72–76 h) may reflect the fact that the CA are not fully developed until 62–64 h after oviposition (Nelson, 1915). Moreover, dorsal closure occurs late in this species, (62–66 h) which is in keeping with the established developmental correlation between dorsal closure and the peak in the embryonic JH titer. It should be noted that the *A. mellifera* embryo does not undergo blastokinesis, thus making it difficult to relate changes in the JH titer with events surrounding and within this process.

As previously noted, the very early presence of JH in the egg of some species has led several investigators to suggest the origin of the hormone at this stage is maternal. In other words, hemolymph JH from the adult female is sequestered by the embryo during the process of vitellogenesis. Gilbert and Schneiderman (1961), in their pioneering work on JH, demonstrated that newly oviposited eggs contain low levels of JH; however, allatectomy of adult gravid females leads to eggs devoid of JH. They, as well as later investigators (Temin *et al.*, 1986; Steiner *et al.*, 1999), proposed that JH is taken up passively by the embryo. Indeed, presupposing that all JH is derived from the CA, this premise would be true, but the possibility remains that extra-allatal sites are involved in JH biosynthesis. Hartmann *et al.* (1987) demonstrated that the serosa of *L. migratoria* is capable of methylation of JH III acid to form JH III. Whether this process can yield sufficient JH to account for the amount of JH detected before dorsal closure is uncertain, nor is it clear whether other insects utilize this unique tissue for biosynthesis of JH. A summary of JH titers during embryogenesis is seen in **Table 2**.

Do these profiles indicate that JH is requisite at key times during embryonic development? Unfortunately, the markers that denote embryological development vary widely among species and make comparisons difficult. For example, blastokinesisis varies radically among species (Johannsen and Butt, 1941) and does not provide an adequate morphological marker to make generalizations. Moreover, while the movements of blastokinesis may appear similar in many species, this process may not necessarily signify a developmentally defining homologous event (Heming, 2003). By contrast, dorsal closure is an anatomical reference point that signifies a specific developmental event. However, an embryonic cell layer, more commonly referred to as a membrane, is known to create a provisional dorsal closure that occurs earlier than the final

Table 2 JH levels during insect embryogenesis[a]

[a]JH titers were determined by GC/MS or HPLC/bioassay.
[b]Low JH titers are those that are less than one-third of the highest level reported.
[c]Medium JH levels are those that fall between one-third and two-thirds of the highest level reported.
[d]High JH levels are those that are greater than two-thirds of the highest level reported.
[e]Blastokinesis is not observed in these species; in these species, JH titers are reported for the period corresponding to approximately half way between oviposition and dorsal closure.

dorsal closure. An example of the confusion this can cause is readily seen in studies of the embryo of *M. sexta*, where a provisional dorsal closure is evident at about 50 h after oviposition (Broadie *et al.*, 1991), while the final dorsal closure becomes apparent only at 102 h after oviposition (Dorn *et al.*, 1987). While knowledge of JH titers offers correlative information when linked to a key point in embryogenesis, it can provide only indirect evidence for the role(s) the hormone plays during this period.

3.7.10.4. Roles of Juvenile Hormone during Embryogenesis

To better understand the embryological roles of JH, two experimental approaches have been taken: chemical allatectomy using precocene and the application of exogenous JH or a JH agonist. Application of JH I or II to eggs of *Thermobia domestica*, an ametabolous insect, any time from oviposition to 2 days before hatching, leads to highly deformed embryos and poor emergence rates (Rohdendorf and Sehnal, 1973). Injeyan *et al.* (1979) applied JH III to *S. gregaria* embryos and found a different pattern of JH-induced disruption. JH applied shortly after oviposition has little effect on embryogenesis, but when applied from days 3 to 9 postoviposition has a profound effect on development, including disruption of blastokinesis, inhibition of postblastokinesis development, and failure of the vermiform larva either to initiate or to complete ecdysis. JH has no effect on embryonic development when applied between day 10 and day 16 (hatching). Disruption of development is accompanied by increased pigmentation of the embryos, and it was discovered that the pigmented regions of treated insects have a much thinner procuticle. In contrast to these results, Sbrenna-Micciarelli (1977) demonstrated that high doses of the analog farnesyl methyl ether applied to the embryo just before blastokinesis induces premature development of the cuticle. Although the results are conflicting, both authors conclude that JH may have a role in cuticulogenesis.

Application of precocene to *N. cinerea* embryos following dorsal closure results in abnormal midgut development, which appears to stem from the failure of ectodermal cells to migrate from the developing stomodaeum and proctodaeum into the midgut rudiments to form the gut epithelium (Brüning *et al.*, 1985). In addition, the absence of JH after dorsal closure leads to disintegration of the fat body and abnormalities in the cuticle. *Oncopeltus fasciatus*

embryos treated with precocene at blastokinesis fail to undergo final dorsal closure, suggesting that JH is involved in development of ectodermal tissue (Dorn, 1982). This developmental aberration can be rescued by topical application of JH. Enslee and Riddiford (1977) demonstrated that blastokinesis in *P. apterus* was vulnerable to exogenous JH, which interfered with dorsal closure and induced truncated appendage development and early pigmentation of developing eye and abdominal structures. These authors suggested that the extraembryonic "membranes" might be the target of JH. Day-old embryos of *R. prolixus*, when treated with high levels of fenoxycarb, do not develop past katatrepsis, and patterns of protein synthesis, as determined by two-dimensional gel electrophoresis, are significantly altered (Kelly and Huebner, 1987). In yet another hemipteran, *Aphis fabae*, precocene inhibits embryogenesis, but the process can be rescued by JH (Hardie, 1987). Interestingly, JH appears to accelerate embryonic development via a mechanism independent of the parthenogenic reproductive strategy employed by aphids.

The effect of JH or analogs on the embryogenesis of holometabolous insects is similar to that seen in hemimetabolous insects. Unfortunately fewer studies have been carried out and all of them utilize the addition of exogenous JH to determine an effect. In Lepidoptera, JH injected into the female prior to oviposition halts embryogenesis at formation of the blastoderm, while JH applied directly to the egg shortly after oviposition has no effect on blastoderm formation, but blocks blastokinesis (Riddiford, 1970). Even without blastokinesis, embryos continue larval differentiation and form recognizable but incomplete first instars, as in *P. apterus* (Enslee and Riddiford, 1977). In another lepidopteran embryo, that of *Plodia interpunctella*, JH agonists induce aberrant dorsal closure and a loss of trachea (Dyby and Silhacek, 1997). A very different situation exists in *D. melanogaster*, a species in which no JH is detected during embryogenesis (Bownes and Rembold, 1987). While JH analogs can disrupt development if applied very early, large doses of JH I do not have an effect on embryogenesis (Smith and Arking, 1975).

The underlying molecular role of JH during embryogenesis is even more obscure. In an early study, Rao and Krishnakumaran (1974) attempted to elucidate the role of JH at the molecular level. When these investigators examined morphological alterations and changes in DNA synthesis in embryos of *A. domesticus* challenged with JH I, they found a qualitative drop in incorporation of thymidine into DNA, as monitored by autoradiography. Embryonic epidermal tissue is the first to show reduced incorporation of thymidine in the presence of exogenous JH; however, some tissues appear refractory to the hormone. Interestingly, JH-treated *A. domesticus* embryos develop legs and antennae that are short and stumpy, which led Rao and Krishnakumaran (1974) to suggest that JH may suppress DNA synthesis and cell division in the embryonic appendages.

Despite the paucity of information, it is tempting to speculate that embryonic ectodermal tissue is a major target of JH. The effects of JH on cuticular morphology, dorsal closure, and pigmentation of embryonic epidermal structures support this idea, and are in keeping with the function of JH during larval development. The fact that JH acts on midgut and fat body development in at least some species indicates there also may be a wider role for the hormone.

3.7.10.5. Juvenile Hormone Binding Proteins of the Embryo

The JHBPs have long been known to modulate the catabolism of hemolymph JH during the larval period (Hammock *et al*., 1975; Roe and Venkatesh, 1990; deKort and Granger, 1996) (see Section 3.7.9). It is generally assumed that JHBP has a unique hormone-binding domain whose steric arrangement hinders the access of catabolic enzymes to JH (Goodman, 1990). While the roles of the hJHBP in larval development are well defined (see Section 3.7.8.3), the role of embryonic JHBP is less clear. It is now clear that significant levels of JHBP are present throughout embryogenesis even though the circulatory system is not yet fully functional until late in development, and JH levels, as noted above, do not rise until the insect is midway through embryonic development.

In *L. migratoria*, a JHBP similar to that found in nymphal hemolymph is present in both the embryo and serosa (Hartmann *et al*., 1987), prior to the development of the CA and a functional circulatory system. These investigators demonstrated that the serosa has a methyl transferase capable of converting JH III acid to JH III, and surmised that the embryonic JHBP serves either to distribute the hormone or to act as a buffer, protecting the embryo from excess maternal JH. The hypothesis of a protective function for embryonic JHBP is supported by the fact that JH levels in the gravid female are at least an order of magnitude higher than in the eggs (Temin *et al*., 1986). Thus, the JHBP could act as a "sponge", keeping the JH accessible to catabolic enzymes that can readily inactivate the hormone.

In *M. sexta*, a hJHBP-like molecule is present at oviposition and remains at detectable levels throughout embryogenesis (Touhara and Prestwich, 1994; Touhara *et al.*, 1994). A re-examination of the characteristics and titers of the embryonic JHBP demonstrated that the embryonic JHBP is identical in binding characteristics (Touhara and Prestwich, 1994; Touhara *et al.*, 1994), molecular mass, and immunochemical properties to the larval hemolymph form (Orth *et al.*, 2003a). Furthermore, the nucleotide sequence of the embryonic *JHBP* gene is identical to that of the larval gene (Orth *et al.*, 2003b); thus, it can be concluded that the embryonic JHBP is identical to hJHBP. Expression of the *JHBP* gene begins in both the embryo and the serosa approximately 15 h after oviposition, peaks between 24 and 36 h, and then declines to undetectable levels at 72 h. The burst of *JHBP* expression occurs before emergence of functional CA, fat body, or circulatory system. In contrast to its gene expression, titers of JHBP are at their highest during the first half of embryogenesis (**Figure 17**). The titer declines rapidly between 36 and 60 h after oviposition and then slowly drops to its lowest level at the time of emergence. The peak of gene expression does not appear to enhance the already high levels of JHBP and the reason for this temporal discordance between gene expression and the JHBP titer is unclear. As in the case of *L. migratoria*, it appears that both the serosa and the embryo of *M. sexta* are capable of expressing *JHBP*. Curiously, the expression of *JHBP* in *M. sexta* begins about 15 h after oviposition, corresponding to the time at which the serosa becomes active in secretion of the first of several embryonic "membranes" (Lamer and Dorn, 2001).

Most of the embryonic JHBP in *M. sexta*, especially in the early hours following oviposition, is maternally derived and is assumed to be sequestered from hemolymph during the process of vitellogenesis. The presence of relatively high levels of the protein prior to development of the CA or circulatory system suggests that, as in *L. migratoria*, high levels of JHBP in the early embryo of *M. sexta* ensure low levels of unbound JH, thus protecting the embryo from excess JH (Orth *et al.*, 2003b). JH bioassay data indicate that hemolymph JH titers in adult female *M. sexta* are as high as those found in the early fourth stadium larvae (Judy, personal communication). Thus, during the early part of embryogenesis, the maternally derived JHBP acts as an effective buffer, constantly binding and releasing the hormone in accordance with equilibrium conditions. Embryonic JHE displays a developmental profile similar to that of JHBP (Share *et al.*, 1988) and together, these proteins regulate bioavailability of the hormone to the developing embryo.

3.7.10.5.1. Juvenile hormone catabolism during embryogenesis: methyl ester hydrolysis Embryonic titers of JH are the result of both biosynthesis and catabolism. While this area has received considerable attention in the larval stage (see Section 3.7.9), scant attention has been focused on these catabolic enzymes in the egg. Roe *et al.* (1987a, 1987b) examined the metabolism of JH in the eggs of the cricket *A. domesticus*. Their studies found that the major route of metabolism is the conversion of JH to JH acid. They reported that general esterase activity, as determined using α-naphthyl acetate as a substrate, remains relatively constant throughout embryonic development. In contrast, JHE activity is high in unfertilized eggs and remains high until the time of dorsal closure, when it drops to its lowest level and remains relatively low until nymphal emergence.

In a very thorough analysis of JH titers (Brüning *et al.*, 1985), JH biosynthetic rates, and JHE activity in *N. cinerea* embryos, Lanzrein and her colleagues demonstrated that JHE activity is very low following dorsal closure (20 days after oviposition) (Bürgin and Lanzrein, 1988). **Figure 18** shows that the massive peak representing both JH III and MF begins to decline very rapidly when JHE activity

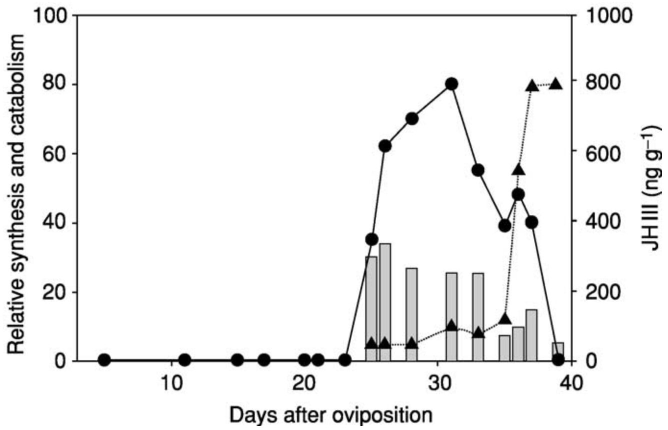

Figure 18 JH titers, JH biosynthetic rates, and JHE activity from *Nauphoeta cinerea* embryos. Closed circles, JH III titers (Brüning *et al.*, 1985); bars, relative JH III biosynthesis as determined by the radiochemical assay (Bürgin and Lanzrein, 1988); closed triangles, JHE activity (Bürgin and Lanzrein, 1988). Dorsal closure occurs at day 20.

rises at day 35. According to these investigators, the rise in JHE corresponds to the period of chorion breakdown; as a result, the increase in available oxygen significantly changes the physiology of the rapidly developing embryo. Interestingly, JHE activity does not appear to be localized to the hemolymph, but rather is distributed generally throughout the entire embryo (Bürgin and Lanzrein, 1988). Since JH III titers in the first instar nymphs are low (1ng g^{-1}), the dramatic rise in JHE activity may be necessary to clear both JH and MF prior to nymphal emergence (Brüning *et al.*, 1985).

The rapid rise in JHE activity observed at the end of embryonic development in *N. cinerea* contrasts with that observed in *M. sexta*. In this insect, JHE activity is high in preovipositional eggs, but declines well before provisional dorsal closure (Share *et al.*, 1988). JHE activity remains relatively constant throughout the rest of embryonic development and does not show the dramatic increase in activity that is observed in *N. cinerea* (Bürgin and Lanzrein, 1988). Despite the presence of JHE activity, JH titers increase dramatically in the period surrounding larval cuticulogenesis (Bergot *et al.*, 1981a). The rise in the JH titer, in the presence of significant JHE activity, contradicts the generally held view that JHE is involved in inactivation of the hormone (see Section 3.7.9.1). It may well be that JH and JHE are sufficiently compartmentalized at the onset of cuticulogenesis that catabolism of the hormone is limited. Once the larval circulatory system is fully functional, approximately 24 h later as determined by vigorous dorsal vessel contraction (Broadie *et al.*, 1991), contact between the hormone and the catabolic enzymes result in a reduced JH titer as the enzyme carries out its anticipated function.

3.7.10.5.2. Juvenile hormone catabolism during embryogenesis: epoxide hydrolysis While most studies on JH catabolism have been focused on the JHEs, a handful of investigators have examined the action of the JHEH (see Section 3.7.9.2). Share *et al.* (1988), in their studies on JH metabolism during embryogenesis in *M. sexta*, demonstrated that JHEH activity is responsible for only a small amount of the total catabolic activity. They found that this enzyme hydrolyzes JH III about six times better than JH I, but they did not take into account the fact that JH I binds to the JHBP with a significantly higher affinity and thus protects the hormone from degradation (Park *et al.*, 1993).

The first characterization of a specific JHEH early in development was carried out by Touhara and Prestwich (1993) in a study of JH metabolism in eggs of *M. sexta*. Using the JH photoaffinity label [^{3}H]epoxyfarnesyl diazoacetate, these investigators demonstrated that the radiolabeled analog covalently attaches to two proteins in the egg, the juvenile hormone binding protein and a 50 kDa protein that was identified as a JHEH. The majority of the JHEH activity is found in the microsomal fraction of the egg homogenate. The purified JHEH displays an apparent K_m of 0.61 μM for JH I and 0.28 μM for JH III, confirming the earlier observation by Share *et al.* (1988) that JH III appears to be the preferred substrate. A subsequent characterization of recombinant JHEH from *M. sexta* reconfirmed this substrate specificity (Debernard *et al.*, 1998). This study also found that the hJHBP protects the hormone from epoxide hydration, but whether this occurs *in vivo* is uncertain since the binding protein is present in the hemolymph (with the exception of the fat body), while the JHEH is localized to the cellular compartment.

3.7.10.6. Juvenile Hormones and the Evolution of Insect Metamorphosis

Truman and Riddiford (1999, 2002) have proposed that the temporal appearance of JH during embryonic development may have played an important role in the evolution of holometabolic insects. Their hypothesis is based, in part, on the idea that ancestral insects displayed three stages after embryogenesis: the pronymph, the nymph, and the adult. The pronymphal stage represents a specialized hatching stage in ametabolous and hemimetabolous insects that is (1) nonfeeding, (2) often mobile, (3) often surrounded by an embryonic cuticle, and (4) different in body proportions from that of the first instar. Depending upon the species, the pronymphal stage is initiated after completion of blastokinesis and may end prior to hatching or persist for several days after hatching. The Truman and Riddiford hypothesis states that the pronymphal and nymphal stages of this insect are developmentally equivalent to the larval and pupal stages, respectively, of the holometabolus insect. Moreover, there is a requirement for a JH-free period in ametabolous and hemimetabolous species that allows nymphal development to proceed towards adult stage.

Can experimental manipulation mimic the evolutionary processes that led to the transition to the holometabolous state? As noted earlier, JH can induce certain tissues in hemimetabolous species to undergo apparent premature differentiation before those tissues are completely patterned. This curious phenomenon has led Truman and Riddiford (1999, 2002) to suggest that the early appearance of JH during embryogenesis, either experimentally or naturally, modifies the developmental trajectory of the holometabolous insect to the adult stage, giving rise to a protolarval stage. From an evolutionary standpoint, advancing the time at which JH appears during embryogenesis may have been crucial to the transition from the pronymphal stage of the hemimetabolous insect to the protolarval stage of holometabolous species. While this hypothesis deserves much merit for simplicity and elegance, it is not without criticism (Heming, 2003). As demonstrated in **Table 2**, JH titers have been rigorously determined in only a handful of species, thus leaving any generalizations about the endocrine-driven rise of holometabolous development open to question. Moreover, working definitions of key embryogenic events, such as blastokinesis and dorsal closure, may be interpreted differently, depending on the investigator. The problem is further compounded by contradictory data on the time at which JH titers rise in relation to the key embryonic events. Truman and Riddiford (2002) suggest that JH titers in the embryo of the lepidopteran *M. sexta* are highest at the time of katatrepsis, yet Ziese and Dorn (2003) place katatrepsis at a time when JH titers (Bergot *et al*., 1981a) are undetectable. Assigning an embryological role to JH when the levels are low raises yet another issue: low JH titers at oviposition and at blastokinesis in some species contradict the hypothesis that a JH-free period is required for further normal development (**Table 2**). While the Truman and Riddiford hypothesis about the rise of holometabolous insects presents an intriguing model that deserves further critical study, the role that JH may have had in this process is still open.

3.7.11. Juvenile Hormones in Premetamorphic Development

3.7.11.1. Juvenile Hormone Titers

The premetamorphic titers of JH appear to vary greatly among the insect orders, with some orders, such as Dictyoptera, displaying levels 100-fold greater than Lepidoptera (Gilbert *et al*., 2000). Yet one pattern has remained constant since the discovery of JH in the 1930s: JH titers, on average, are high while the larva is growing and feeding but drop at a well-defined point to permit metamorphosis. This pattern can be further refined to distinguish between hemimetabolous and holometabolous insects (Riddiford, 1994). In hemimetabolous insects, JH titers are low to undetectable during the final stadium. In holometabolous insects, JH titers are relatively high at the beginning of the final larval stadium but decline to undetectable levels prior to the cessation of feeding. The absence of JH permits the release of the prothoracicotropic hormone (PTTH) from specific cerebral neurosecretory cells (Rountree and Bollenbacher, 1986), and PTTH then induces ecdysteroid synthesis by the prothoracic glands, initiating a small rise in hemolymph ecdysteroid levels (Bollenbacher *et al*., 1981) (see **Chapter 3.2**). This rise in the ecdysteroid titer in the absence of JH initiates metamorphosis. In contrast to the hemimetabolous insects, a second increase in the hemolymph JH titer is typically observed after the insect has found a suitable pupation site. This peak in the titer is thought to prevent precocious adult differentiation of imaginal discs and other imaginal precursors (Riddiford, 1994).

3.7.11.2. Potential Problems with Titer Determinations

One of the major impediments to better understanding the role(s) of JH is the lack of precise titers

during biologically relevant periods. Virtually all hormones studied in vertebrates display daily oscillations in their titer and release and are, in many cases, linked to critical homeostatic events (Czeisler and Klerman, 1999). Early studies demonstrated a daily, bimodal, rhythmic fluctuation in the size of the nuclei in CA of adult *D. melanogaster* (Rensing, 1964). While size of the CA cells does not necessarily indicate a gland active in JH biosynthesis (Tobe and Stay, 1985), there is ample evidence that indicates enlarged glands are biosynthetically active (Chiang *et al*., 1989, 1991). Thus, fluctuations in CA cell size suggests circadian fluctuations in JH synthesis.

The importance of examining titer fluctuations in detail can be seen in the elegant work from Steel's laboratory, which demonstrates a circadian rhythmicity of ecdysteroid titers in nymphal *R. prolixus* (Steel and Ampleford, 1984; Vafopoulou and Steel, 2001) (see **Chapter 3.11**). A single-point JH determination every 24 h may not be a serious problem for the student of metamorphosis, where JH-regulated events stretch over a period of several days. However, it does make a difference when relatively rapid changes in JH titer regulate critical cellular events that occur during a short time period. Recent studies demonstrating that JH titers fluctuate rapidly in adult insects supports the premise that detailed studies of JH titers during the premetamorphic stages are needed. Elekonich *et al.* (2001) found that honeybee foragers show a diurnal increase in hemolymph JH titers, from about 100 ng ml^{-1} in the late morning to over 350 ng ml^{-1} by late evening, a period spanning less than 12 h. A similar change is seen in the fourth stadium of *M. sexta*, where titers initially rise and then drop significantly over an 8 h period and may have some influence on levels of the transport protein, hJHBP (Fain and Riddiford, 1975; Orth *et al*., 1999). This is not to infer that JH titers must be absolutely accurate; the important information is knowledge of changes in the relative titers at well-defined times.

However, even if precise staging is possible, the measurement of JH in samples from species or stages displaying low levels of hormone, or from smaller sized species, requires that tissue collections be pooled from a number of individuals. Valuable information about population variability is thus lost. Ideally, a single individual should be sampled sequentially over time, but this process leads to wound-induced changes (Caveney, 1970) that may significantly alter JH titers. In our hands, wounding has rapid and significant effects on hJHBP mRNA expression, which potentially modulates JH titers (Orth and Goodman, unpublished data). Even moderate handling prior to sample collection may have an effect on JH titers (Varjas *et al*., 1992).

3.7.11.3. Premetamorphic Roles of the Juvenile Hormones

The roles of JH in the stages preceding metamorphosis to the adult are ubiquitous, affecting behavior, organs and tissues, cellular organelles, and biochemical pathways. Several excellent reviews have covered these areas (Nijhout, 1994; Riddiford, 1994, 1996), and the focus here is on research since that time.

3.7.11.3.1. Behavioral and neuronal responses There are a number of behavioral phenomena ascribed to JH during the adult stage, including pheromone production and calling (review: Cusson *et al*., 1994), migration (review: Dingle and Winchell, 1997), phonotaxis (Stout *et al*., 1992, 1998; Bronsert *et al*., 2003), and caste determination and anatomical changes in the brain of honeybees (reviews: Robinson and Vargo, 1997; Elekonich and Robinson, 2000) (see **Chapter 3.13**). However, little is known about the effect of JH on behavior during the premetamorphic period, and most of these studies have been done in social or migratory insects.

Late in the third stadium, honeybee larvae destined to become queens have JH titers five times higher than larvae destined to become workers (Rachinsky and Hartfelder, 1991; Rembold *et al*., 1992) (see **Chapter 3.13**). In another hymenopteran, the ant *Phiedole bicarinata*, large doses of methoprene, if applied during a critical period in the last stadium, induce worker-destined larvae to become soldiers (Wheeler and Nijhout, 1981). Higher JH titers during the last stadium of certain migratory species appear to elicit a stationary adult stage, rather than migration (Yagi and Kuramochi, 1976; Nijhout and Wheeler, 1982). Yin *et al*. (1987) demonstrated that methoprene can affect the circadian system in the lepidopteran *Diatraea grandiosella*, inducing a dose-dependent phase shift in adult eclosion.

At the neuronal level, most endocrine studies have focused on the effect of ecdysteroids on the neural circuitry during metamorphsis (see **Chapter 2.4**), although JH appears to play a role as well. Truman and Reiss (1988) demonstrated that reorganization of neurons during metamorphosis of *M. sexta* is, in part, under the control of JH, but the regulatory elements involved are still undefined. Recent work suggests that JH affects larval neurons innervating the prothoracic gland of the cockroach *P. americana* (Richter and Gronert, 1999). Exposure of the insect to exogenous JH III and methoprene both *in vivo* and *in vitro* induces a short-term depression of spike

activity in neurons innervating the prothoracic gland, but has no effect on the nervous connectives of the stomatogastric nervous system. This response to JH III is very rapid, occurring within 3 min of treatment and reaching a low (75% reduction) within 15 min. Curiously, fenoxycarb, a potent JH analog, was only half as active as JH III and methoprene; methyl laurate, a control lipid, had no effect. The authors speculate that JH is acting directly on membrane receptors to elicit the reduced neurotropic activity; this observation relates to an earlier hypothesis that JH can influence inhibitory neurotransmitter receptors such as γ-aminobutyric acid (GABA) (Stout *et al.*, 1992).

3.7.11.3.2. Epidermal responses It has long been known that JH has a marked influence on epidermal and cuticular structure. The early work of Williams (1952) demonstrated that JH-containing extracts, when applied at a developmentally sensitive time during the pupal period, can induce a second pupal cuticle. This discovery prompted Williams to suggest that JH is a "status quo" hormone, a label that is still in frequent use (Willis, 1996). The integument of the insect is composed of an outer layer of secreted proteins, lipids, pigments, and complex carbohydrates termed the cuticle. The single layer of cells immediately beneath the cuticle, the epidermis, is responsible for synthesis and secretion of most, but not all, of the proteins found in the cuticle (Willis, 1996). The epidermis itself contains another subset of proteins, pigment-associating proteins, the expression and position of which in the cells appear to be regulated by JH. The radical changes in morphology at metamorphosis led Wigglesworth (1959) to predict that each stage of development had its own set of unique genes. While there does appear to be a limited group of stage-specific cuticular proteins, especially in the case of the higher flies, current evidence demonstrates that many cuticular proteins can be found in more than one stage of the life cycle (review: Willis, 1996).

Hormonal regulation of epidermal gene expression has been examined in a number of insect species, but the most extensive studies, by Riddiford and her colleagues, have been carried out on the epidermal genes of *M. sexta* (Riddiford, 1994, 1996; Riddiford *et al.*, 2001, 2003). These include the larval cuticular protein 14 (LCP14) (GenBank Accession no. 813279) (Rebers and Riddiford, 1988), LCP14.6 (GenBank Acc. No. U65902) (Rebers *et al.*, 1997), LCP16/17 (GenBank Accession no. M25486) (Horodyski and Riddiford, 1989), the biliverdin-associating proteins, insecticyanin a and b (GenBank Accession nos. 864714 and 864715) (Li and Riddiford, 1992), and dopa decarboxylase (DDC) (GenBank Accession no. U03909) (Hiruma and Riddiford, 1988; Hiruma *et al.*, 1995). Studies using the epidermis are particularly compelling, since the results of *in vitro* manipulations mirror those observed *in vivo*, and importantly, the genomic structure and flanking regions of their genes have been determined.

LCP14 is a larval-specific gene that encodes for a 14 kDa protein expressed during the feeding period of each stadium (Riddiford, 1994). At the onset of a larval molt, mRNA for LCP14 rapidly becomes undetectable and remains so until the insect molts to the next stadium, at which time the expression levels rise again and the process repeats itself. In the last stadium, levels of LCP14 message rise during the first several days, but fall sharply prior to wandering and are no longer detectable. *In vitro* manipulation indicates that 20E suppresses the expression of this gene. If JH is present when 20E titers rise, suppression by 20E is only transient; if JH is absent, the gene is permanently silenced. While it is uncertain how JH acts at the molecular level to maintain the expression of *LCP14*, its function may involve the transcription factor βFTZ-F1. It has been shown that there are three potential binding sites for βFTZ-F1 in the *LCP14* gene, one approximately 2 kb upstream from the start site and two in the first intron (Lan, personal communication). The expression of *βFTZ-F1* begins about 16 h before molting, peaks at about 9 h before molting, and then ceases approximately 3 h before molting (Weller *et al.*, 2001). Functional analysis of the putative *LCP14* promoter indicates that the βFTZ-F1 response elements in the first intron are involved in downregulating *LCP14* expression (Lan, personal communication). The decline in βFTZ-F1 expression coincides with the rise in JH at the very beginning of the fifth stadium and with it, the increase in *LCP14* expression. Whether JH acts directly on the gene, or is involved in modulating the ecdysteroid effect, remains unclear.

LCP14.6 is another hormonally controlled cuticular gene, which, like *LCP14*, is downregulated by 20E, but in contrast to *LCP14*, is suppressed *in vitro* by large doses of methoprene (Riddiford, 1986). Its expression is temporally and spatially complex and is not stage-specific, since it occurs in the larval, pupal, and adult stages. A comparison of its expression pattern with the JH titer profile suggests that, *in vivo*, *LCP14.6* expression may be suppressed by the hormone. *LCP16/17* encodes a multigene family of three proteins that appear midway through the feeding period of the fifth stadium (Horodyski and Riddiford, 1989). The developmental appearance of

these proteins correlates with a thinning of cuticular lamellae and a corresponding increase in stiffness. Like *LCP14.6*, expression of the *LCP16/17* is suppressed by large doses of methoprene.

One of the more striking effects elicited by JH is its action on larval pigmentation (Nijhout, 1994; Applebaum *et al.*, 1997). Nowhere is this more evident than in larval *M. sexta*, where two mutants have been discovered with anomalous pigmentation and aberrant JH titers. In the *bl* mutant (Safranek and Riddiford, 1975), JH titers are low at certain critical developmental points and the larvae are highly melanized; in the white mutant, the opposite is the case (Panchapakesan *et al.*, 1994). To maintain the normal wild-type phenotype following a molt, i.e., a transparent cuticle and an epidermis with intracellular vesicles containing the biliverdin-associating protein, insecticyanin (Riley *et al.*, 1984; Goodman *et al.*, 1985), JH titers must be sufficiently high at the time of head capsule slippage (Hiruma and Riddiford, 1988; Riddiford, 1994). If JH titers are too high at the time of head capsule slippage, the resulting cuticle will be transparent, and the underlying epidermal cells will lack insecticyanin vesicles, causing the insect to appear white (Panchapakesan *et al.*, 1994). Conversely, if JH titers are too low at the time of head capsule slippage, the resulting cuticle will be highly melanized and the epidermis devoid of insecticyanin vesicles, causing the insect to appear black (Goodman *et al.*, 1987).

Insecticyanin (Ins) is a 21 kDa protein that associates with biliverdin IX to yield an intensely blue protein important to larval camouflage (Goodman *et al.*, 1985). Ins is found in epidermal cells, where it is sequestered in 1 μm vesicles (**Figure 19**). These vesicles, together with other epidermal and cuticular pigments, give the wild-type insect its distinctive blue–green hue during the feeding period (Riddiford *et al.*, 1990). Analysis of epidermal ultrastructure indicates that the densely packed vesicles appear to be held in position by a web of microtubules (Goodman, unpublished data). A typical wild-type epidermal cell contains approximately 100 of the membrane-coated vesicles, localized in the apical region. The epidermal cell also secretes significant quantities of Ins into the hemolymph, making it one of the more prominent hemolymph proteins (Riddiford *et al.*, 1990). At commitment to pupation, when JH is no longer present and ecdysteroid levels rise, the entire population of Ins-containing vesicles is secreted from the epidermal cell (Sedlak *et al.*, 1983) and the insect ceases production of the protein (Goodman *et al.*, 1987; Riddiford *et al.*, 1990). Interestingly, the *bl* mutant, which has a low JH titer at head capsule slippage, lacks the epidermal Ins-containing vesicles, thus mimicking the ultrastructure of the wandering fifth stadium epidermis. Topical application of JH to *bl* mutants, just prior to head capsule slippage, will induce the appearance of the Ins vesicles in the next stadium, similar in number and position to those in the wild-type (Goodman *et al.*, 1987) (**Figure 19**). Moreover, JH, when applied at head capsule slippage, prevents cuticular melanization in the next stadium (Safranek and Riddiford, 1975). The role of JH in this process is still unclear but ultrastructural data suggests that the cytoskeleton may be involved in retaining the Ins vesicles in the apical portion of the epidermal cell.

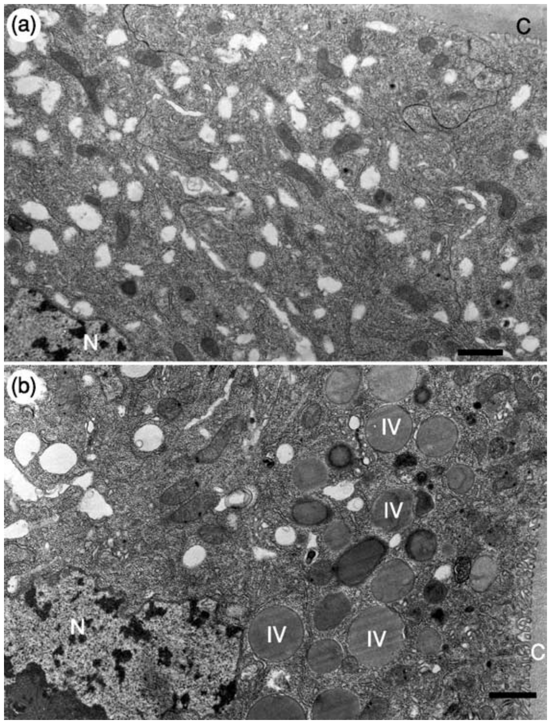

Figure 19 Electron micrographs of the epidermis of the *bl* strain of *M. sexta*. Fourth instars, just prior to head capsule slippage, were treated with either acetone (a) or 50 ng JH I dissolved in acetone (b). Tissue was collected approximately 30 h later, at the time of the fifth larval ecdysis, and prepared for microscopy. C, cuticle; IV, insecticyanin vesicle; N, nucleus. Scale bars represent 1 μm. (Goodman, unpublished data.)

In addition to the presence of Ins mRNA in the epidermis of wild-type larvae, Ins mRNA has also been found in the fat body (Li and Riddiford, 1994; Li, 1996); however, the protein could not be detected immunologically unless pericardial cells were included in the preparation (Goodman *et al.*, 1987). Curiously, JH appears to upregulate epidermal Ins mRNA abundance, while it downregulates this mRNA in the fat body (Li, 1996). As in the case of *LCP14*, 20E downregulates the epidermal Ins mRNA (Riddiford *et al.*, 1990) during the molting period.

Cloning of the *Ins* gene revealed a pair of duplicated genes termed *Ins a* and *Ins b* (Li and Riddiford, 1992) that are expressed in both the epidermis and fat body. Only the product encoded by the *Ins b* gene is found in the hemolymph (Riddiford, 1994). The difference in expression patterns between *Ins a* and *Ins b* led Li (1996) to investigate the structure of the genes, to determine whether different promoters were involved. Each of the genes displays a unique sequence in the 3′ noncoding region, suggesting differential expression. Preliminary computational analysis of the 5′ upstream region of *Ins a* indicated no known response elements (Lan, personal communication).

DDC is the enzyme responsible for catalyzing the conversion of dopa to dopamine (Hiruma and Riddiford, 1984) while granular phenoloxidase (PO) catalyzes the oxidative dehydrogenation of diphenols to quinones (Hopkins and Kramer, 1992) (see **Chapter 4.4**). For cuticular melanization to occur, vesicles containing dopamine, the granular proenzyme form of PO, and other enzymes necessary for melanin synthesis are secreted into the new endocuticle following head capsule slippage. If JH titers are low or absent at the time of head capsule slippage, the proenzyme form of PO will be synthesized by the epidermis and deposited in the endocuticle for a period of approximately 12–14 h. Approximately 3 h before ecdysis, PO is activated, possibly by proteolytic activation (Jiang *et al*., 2003), and melanin begins to appear in the new cuticle. Topical application of JH to *bl* larvae, or to wild-type larvae that have been neck-ligated at head capsule slippage, will block phenoloxidase activity, and a new transparent cuticle will be formed (Riddiford *et al*., 2003). While JH suppresses cuticular melanization in a striking fashion, it remains unclear whether the hormone is acting on transcription or translational events that regulate PO activity.

Hormonal regulation of epidermal DDC (EC 4.1.1.28) in *D. melanogaster* and *M. sexta* has been extensively studied by the Hodgett (Chen *et al*., 2002a, 2002b) and Riddiford laboratories (Riddiford, 1994; Riddiford *et al*., 2003). In *M. sexta*, 20E works directly on epidermis to block DDC synthesis; however, as the ecdysteroid titers decline during the head capsule slippage period, levels of DDC begin to rise and they peak near the time of the larval molt. A study of the 5′ upstream region of the *DDC* gene indicates that there are several transcription factor binding sites, including a βFTZ-F1 response element between the TATA box and the transcriptional start site (Hiruma *et al*., 1995). Recently, Beckstead *et al*. (2001) demonstrated that the *D. melanogaster* gene *bonus* (*bon*) encodes a homolog of the vertebrate TIF1 transcriptional cofactors. Among the many phenotypes associated with this gene is pigmentation (Beckstead *et al*., 2000). *Bon* binds to the AF-2 activation domain present in the ligand-binding domain of βFTZ-F1 and behaves as a transcriptional inhibitor *in vivo*. A transcription factor implicated in regulation of melanization as well as metamorphosis is the Broad-complex (Br-C). In the metamorphosis of *D. melanogaster*, Br-C is a required mediator in the *DDC* response to ecdysteroids. At pupariation and at eclosion, Br-C uncouples *DDC* from an active silencing mechanism that functions through two distinct *cis*-acting regions of the *DDC* locus (Chen *et al*., 2002a, 2002b). While much is known about *DDC* and its regulation via ecdysteroids, the role of JH in its control remains unclear (Hiruma *et al*., 1995; Chen *et al*., 2002a, 2002b; Riddiford *et al*., 2003). It has been demonstrated that the epidermis of allatectomized *M. sexta* larvae displays approximately 50% more DDC activity than epidermis from sham-operated insects, and that activity of the enzyme can be suppressed by moderate levels of JH I. While this observation is certainly provocative, it remains to be seen whether the JH effect on *DDC* expression is direct, or as some speculate, indirect (Hiruma, personal communication).

3.7.11.3.3. Fat body responses The premetamorphic fat body is responsible for metabolism of nutrients, synthesis of most hemolymph proteins, and detoxification of xenobiotics (Locke, 1984; Sondergaard, 1993; Haunerland and Shirk, 1995). Given the central roles this tissue plays, it is not surprising that an extensive body of literature has focused on the role of JH in regulating cellular and molecular events occurring in the fat body.

Numerous studies involving hormonal regulation of ultrastructural changes in adult fat body, especially those regarding vitellogenesis (see **Chapter 3.9**), have been conducted, but few have focused on the ultrastructural changes induced by JH in the larval fat body. Such experiments are problematic since JH titers are already relatively high during most of larval life, and challenging the fat body with additional JH may result in pharmacological responses that mask the actual underlying events. Thus, the most comprehensive studies are developmental, correlating JH titers with ultrastructural changes occurring during the premetamorphic and metamorphic periods (Locke, 1984; Dean *et al*., 1985). In one series of studies, it was found that during the last stadium of both hemimetabolous

and holometabolous insects, when JH titers are dropping, the fat body synthesizes and secretes several hexameric proteins collectively termed storage proteins (Levenbook, 1985). These proteins are retrieved from the hemolymph by the fat body and stored in relatively large vesicles for later use during the pupal–adult transformation (Locke, 1984; Dean *et al.*, 1985). It has also been demonstrated that a JH analog affects fat body nuclei. Treatment of nymphal *L. migratoria* with high levels of methoprene leads to an increase in the size of fat body nuclei, which could be linked to either increased transcription rates or to increased ploidy levels (Cotton and Anstee, 1991). The latter option seems likely, since Jensen and Brasch (1985) demonstrated that allatectomy of adult *L. migratoria* prevents polyploidization, while methoprene restores the process.

At the molecular level, the role of JH on fat body gene expression has been studied by a number of investigators in several different insect species. Certain of these gene targets are discussed below (see Section 3.7.12), and a comprehensive discussion of the various fat body genes thought to be under the control of JH has been presented by Riddiford (1994). One of the most well-studied groups of premetamorphic fat body genes and proteins is the hexamerins (Burmester *et al.*, 1998; Burmester, 2002). The insect hexamerins encompass at least five different subgroups based on amino acid sequence, including: the coleopteran and dictyopteran JH-suppressible arylphorins, the lepidopteran JH-supressible hexamerins, lepidopteran aromatic amino acid-rich arylphorins, the lepidopteran methionine-rich hexamerins, and the dipteran arylphorins (Beintema *et al.*, 1994). The products encoded by the hexamerin genes are expressed predominantly during late larval life, and thus appear to be negatively regulated by JH. Another group of proteins in the hexamerin superfamily are the hemolymph cyanoproteins (Miura *et al.*, 1998) and the orthopteran hemolymph JH binding proteins (Koopmanschap and deKort, 1988; Braun and Wyatt, 1996). As first demonstrated by Jones *et al.* (1988, 1990a), the expression patterns of certain fat body genes are downregulated by JH and JH analogs; however, exceedingly high doses of JH analogs were used to elicit the responses. More recently, Hwang *et al.* (2001) and Cheon *et al.* (2002) have isolated two genes encoding hexamerins that are JH-suppressible at low doses of JH analog. Expression of these genes is not dose-dependent, but can be downregulated within a 6 h period, suggesting that JH is acting directly on transcription. Thus, a general pattern is emerging that indicates fat body hexamerin expression is suppressed in the presence of JH.

While few insect endocrinologists would argue with the idea that the fat body is a target for JH, there remain technical difficulties in working with the fat body. Its cellular heterogeneity, massive tracheal penetration, and apparent sensitivity to wounding or to culture *in vitro* make experimental manipulation of the premetamorphic fat body difficult. More troubling is the fact that many of the studies lack a dose–response curve, and data are based on a single large dose of hormone or analog. As demonstrated by Orth *et al.* (1999) in their study on JH regulation of *hJHBP* expression, the effect of increasing doses of JH on the fat body is stimulatory only within a limited range; after peak stimulation is reached, further increases in JH result in a negative response. In this case, a single large dose of hormone would have obscured very important data. Another issue with many of the studies is the lack of authentic controls, especially for experiments *in vitro*. Large doses of JH can form a monolayer at the surface of the medium, hindering gaseous exchange and compromising the physiology of the fat body in culture. Unless a comparable lipid is used as a control, the results may be meaningless. It is anticipated that technological advances, particularly in molecular analyses, coupled with a more physiological approach to hormone treatment, should ultimately reveal how JH functions with respect to the fat body.

3.7.11.3.4. Muscle responses Myogenesis occurs during two developmental periods: the embryonic period in which larval muscles are developed and the period of larval–pupal metamorphosis, in which adult muscles are formed. In addition to myogenesis, existing larval muscles can undergo cell death, or become restructured and/or reoriented for a new role in the adult (Riddiford, 1994; Roy and Vijay Raghavan, 1999). At the present time there is little evidence to suggest that JH has a direct role on embryonic myogenesis; however, JH involvement in the regulation of muscle development and muscle fate during metamorphosis is well documented (Schwartz, 1992; Riddiford, 1994; Hegstrom *et al.*, 1998; Roy and VijayRaghavan, 1999; Buszczak and Segraves, 2000; Cascone and Schwartz, 2001; Lee *et al.*, 2002). The fate of larval muscles is determined by a finely tuned interplay between JH and ecdysteroids, an example of which is found in the process of proleg retraction in *M. sexta* (Weeks and Truman, 1986a, 1986b). After the larva wanders in the last larval stadium, the prolegs are no longer required, and muscles that move these structures begin to degenerate. The signal for this process is the commitment peak in the ecdysteroid titer, which occurs in the absence of JH. Under these conditions,

the retractor muscles become committed to undergo apoptosis (programmed cell death) (see **Chapter 2.5**), with the actual process of degradation elicited by the large prepupal peak of ecdysteroids that occurs several days later. Despite its concurrent presence at the time of the prepupal peak in the ecdysteroid titer, JH can no longer inhibit apoptosis of the retractor muscles.

Adult-specific muscles are formed from specific myoblasts that proliferate and differentiate during the late larval or early pupal stages (Roy and VijayRaghavan, 1999) (see **Chapters 2.1** and **2.3**). In those muscles that make up the larval ventral diaphragm of *M. sexta*, proliferation and differentiation are controlled by ecdysteroids, but these two events have different hormonal requirements (Champlin *et al*., 1999). Moderate levels of ecdysteroids induce proliferation of the ventral diaphragm myoblasts, while high or low doses arrest cellular proliferation in the G_2 phase of the cell cycle in these cells. High doses of ecdysteroids, such as those observed at the prepupal peak, induce the myoblasts to exit the cell cycle and express muscle myosin. The ability of critical titers of ecdysteroids to initiate either proliferation or differentiation is modified in the presence of methoprene. For example, high levels of ecdysteroids induce myoblast proliferation, but are unable to induce myoblast differentiation, in the presence of methoprene. These experimental observations correlate well with myoblast development *in vivo*. The prepupal peak of ecdysteroids, which is sufficient to induce differentiation, is accompanied by a concomitant rise in JH that prevents the myoblasts from differentiating. The myoblasts continue to proliferate until day 7 of the pupal stage when, in the presence of the pupal ecdysteroid peak but in the absence of JH, they then begin to differentiate. While both the prepupal and pupal surges of ecdysteroids are sufficient to cause differentiation, the pupal surge is not accompanied by a rise in JH levels, thus allowing the myoblasts to differentiate.

A similar interplay between JH and ecdysteroids is observed in the development of flight muscle in the desert locust, *S. gregaria*. Flight muscle development is initiated at the beginning of the last nymphal stadium and completed shortly after adult metamorphosis (Wang *et al*., 1993). In addition to its fully differentiated myofibrils, functional flight muscle contains a high level of a fatty acid binding protein that is involved in sequestering lipids for energy. Flight muscle development begins during the fifth nymphal stadium, when JH is absent and ecdysteroid titers are high. When a large dose of methoprene is applied to the last-stadium nymph, the insect undergoes another nymphal molt, and flight muscles that should have formed working myofibrils remain undifferentiated and lack fatty acid binding protein. Thus, elevated JH titers in the last nymphal stadium can lead to either retention of nymphal muscle or delay in the development of adult muscles.

In the adult stage, JH can have the opposite effect on muscles, inducing them to undergo degradation to yield precursors for vitellogenin production (Rose *et al*., 2001). Treating the alate or winged form of the aphid *Acyrthosiphon pisum* with a JH analog initiates histolysis of indirect flight muscles via the ubiquitin-dependent pathway for apoptosis (Kobayashi and Ishikawa, 1994). Conversely, treatment with precocene II, a compound that reduces JH biosynthesis in this species, prevents flight muscle breakdown. A similar situation is found in another aphid species, *A. fabae* (Hardie *et al*., 1990). The development of flight muscle in Orthoptera appears to follow this same pattern, i.e., JH either induces and/or is involved in the histolysis of these muscles. Application of JH III or methoprene to the cricket *Modicogryllus confirmatus* induces the degeneration of flight muscles within 3 days (Tanaka, 1994). In addition to JH, there may be neural factors that are required for the degeneration of specific flight muscles (Shiga *et al*., 2002).

3.7.11.3.5. Prothoracic gland responses It has long been known that the prothoracic glands, the site of synthesis of ecdysteroids, are regulated by ecdysone itself, via short positive and negative feedback loops (Williams, 1952; Siew and Gilbert, 1971; Sakurai and Williams, 1989) (see **Chapter 3.8**). Given the close relationship between JH and ecdysteroids in regulation of metamorphosis, the effect of JH on the prothoracic glands has also been examined (Gilbert, 1962; Siew and Gilbert, 1971). JH has two separate and distinct effects: prevention of precocious degeneration of the glands and regulation of ecdysteroid synthesis/secretion during the larval stage. In *M. sexta*, the prothoracic glands undergo apoptosis between 5 and 6 days after pupation, at the time of the pupal peak in the ecdysteroid titer. Dai and Gilbert (1999) demonstrated that early pupal glands, in the presence of ecdysteroids *in vitro*, will also undergo apoptosis. Glandular degeneration can be delayed for up to a week, if a newly molted pupa is injected with a large dose of JH II. Moreover, the glands remain capable of synthesizing ecdysone (Dai and Gilbert, 1998). The underlying mechanisms by which JH prevents this important developmental event is still unclear.

Nijhout (1994), in his elegant review of JH effects on ecdysteroid synthesis, came to the conclusion

that JH does not act directly on the prothoracic glands to modulate ecdysone biosynthesis. His model suggests that elevated levels of JH during the early part of the last larval stadium act on the brain (or other intermediary tissue) to suppress synthesis or release of PTTH, the hormone responsible for stimulating ecdysteroidogenesis in the prothoracic glands. It is only when the JH titers drop that PTTH can be released to initiate commitment to pupation by stimulating synthesis of the commitment peak in the ecdysteroid titer (Nijhout and Williams, 1974; Rountree and Bollenbacher, 1986). The idea that the brain is the major target is supported by the work of Gruetzmacher *et al.* (1984), who demonstrated that although PTTH could stimulate *M. sexta* prothoracic gland activity *in vitro*, none of the JH homologs or methoprene, even at a number of different doses, were able to do so. Evidence presented by Sakurai *et al.* (1989) suggests that JH not only acts on the brain but also on the glands themselves, to directly suppress the acquisition of competence to respond to PTTH. Thus, under normal physiological conditions in the last larval stadium, the JH-regulated inhibition of PTTH secretion and suppression of gland competence probably evolved as a safety mechanism to prevent the premature onset of the metamorphic molt (Nijhout, 1994).

While it is accepted that high levels of JH inhibit PTTH production or secretion during the feeding period of the last larval stadium, this does not appear to be the case either in the earlier stadia or after commitment to pupation. In the earlier stadia, JH titers are high to maintain the larval state. Presumably, these high levels of JH should inhibit PTTH secretion, yet the insects undergo normal molts. In early studies, the implantation of extra CA into penultimate and last instars of *G. mellonella* invariably led to perfect supernumerary molts, often more than one (Granger and Sehnal, 1974; Sehnal and Granger, 1975). In more recent studies, supplementing normal JH titers with an analog, fenoxycarb, did not block third and fourth instars of *B. mori* from undergoing normal molts to fourth and fifth instars; however, an extra molt to a perfect sixth instar was noted (Kamimura and Kiuchi, 2002). An identical result was seen in *M. sexta* using methoprene (Lonard *et al.*, 1996). An *in vitro* study provides a basis for the results of these *in vivo* experiments. Addition of fenoxycarb to incubations *in vitro* of *B. mori* prothoracic glands taken throughout the last stadium results in an extreme suppression of ecdysteroidogenesis (Dedos and Fugo, 1996). Although a recent report has shown that JH I, applied in large doses early in the last larval stadium, can transiently elevate PTTH levels in the hemolymph of *B. mori* (Mizoguchi, 2001), the majority of the studies done so far indicate that in contrast to the model for JH–ecdysteroid interaction during larval–pupal metamorphosis, JH is capable of acting directly on the prothoracic glands and does so by suppressing ecdysteroid synthesis.

Biochemical evidence supports this contention: hydroprene, a JH analog, and JH I significantly delay the ability of the prothoracic glands to respond to PTTH or MIX, an inhibitor of cyclic nucleotide phosphodiesterase (Gu *et al.*, 1997). Since PTTH activates an intracellular second messenger system involving cyclic nucleotides (Gilbert *et al.*, 2000) (see **Chapter 3.2**), MIX can serve as a surrogate for PTTH by inhibiting their catabolism. The fact that neither PTTH nor MIX can activate ecdysteroidogenesis in the presence of JH strongly reinforces the idea that JH can act directly on the glands.

Several groups have demonstrated that the effect of JH on the prothoracic glands changes after commitment to pupation. Insects that have been debrained or neck-ligated to remove the source of PTTH respond to JH or analog treatment with increased ecdysteroid synthesis (Hiruma *et al.*, 1978; Safranek *et al.*, 1980; Gruetzmacher *et al.*, 1984; Dedos and Fugo, 1996; Dai and Gilbert, 1998). Thus, a reversal in hormone action appears to have taken place at, and possibly as a result of, commitment. As we have seen with other tissues, the response to JH can vary depending upon the developmental period. In the case of the prothoracic glands, the regulatory processes that control ecdysteroidogenesis and involve JH are very complex.

3.7.12. Molecular Mode of Action of the Juvenile Hormones

No sooner had the chemical structure of JH I been reported by Röller *et al.* (1967), one of the first of many reviews on JH action at the molecular level appeared in print (Kroeger, 1968). Since that time, there have been a number of major reviews focusing on the topic, with at least nine appearing during the last dozen years (Kumaran, 1990; Riddiford, 1994, 1996; Jones, 1995; Wyatt and Davey, 1996; Gade *et al.*, 1997; Gilbert *et al.*, 2000; Lafont, 2000; Wheeler and Nijhout, 2003).

Despite the volumes written about the subject, the molecular action of JH remains very much a mystery. This has led some to suggest that JH may have multiple roles in cellular and molecular mechanisms (Jones, 1995; Wheeler and Nijhout, 2003). Our assessment of the literature suggests that some of the problems in deciphering the molecular action

of JH lie not in unfathomable molecular mechanisms, but rather in the quality of the hormone, choice of experimental model, and development of experimental design.

A major experimental pitfall is the quality of the hormone, especially commercially available JH III from a US supplier. The supplier acknowledges that the hormone is racemic and the level of contamination is significant. Yet there appears to be a tacit assumption among investigators that the unnatural racemate and contaminants have no effect on the experimental procedure, an assumption that is unwarranted until proven. Long-term storage of the hormone and its metabolites may also be problematic and a means of repurifying the compounds must be available. A similar criticism can be leveled at the use of commercial-grade JH agonists that may contain significant amounts of incipients with unknown biological functions.

Metamorphosis is undoubtedly one of the most striking phenomena in the biological world, yet it has not yielded its molecular secrets easily, particularly with regard to JH action. While major strides have been made in the last few years, using a paradigm that depends on the absence of JH makes dissecting the molecular action of the hormone challenging. This problem is further compounded by the fact that the metamorphic actions of JH on cellular and molecular events often require lengthy incubation periods. These long periods make separating key regulatory events from secondary events difficult. It may well be that the extreme complexity of metamorphosis does not lend itself well to isolating the actions of JH, and, as Jones (1995) and Wheeler and Nijhout (2003) note, the hormone may act on a number of molecular pathways in the same cell. As our knowledge of larval physiology and molecular biology expands, nonmetamorphic events regulated by JH, such as pigmentation and metabolic processes, may provide more tractable experimental models with which to study the molecular actions of JH at the genomic level.

3.7.12.1. Juvenile Hormone Interaction with Ultraspiracle

One of the more intriguing discoveries since the last major reviews is that presented by Jones and Sharp (1997), who demonstrated that the nuclear receptor Ultraspiracle (USP) can bind JH III (see **Chapter 3.5**). USP, an orphan receptor for which no endogenous ligand has been unambigiously established (Billas *et al.*, 2001), is a heterodimeric partner that interacts with ECR to form the functional ECR complex (Thomas *et al.*, 1993; Yao *et al.*, 1993) or with DHR38, the *D. melanogaster* ortholog of the mammalian NGFI-B subfamily of orphan nuclear receptors (Baker *et al.*, 2003) (see **Chapter 3.5**). USP is an ortholog of the vertebrate retinoid X receptor (RXR) (Oro *et al.*, 1990), which is responsive to very high levels of methoprene (Harmon *et al.*, 1995).

Using a fluorescence assay that detects changes in protein conformation induced by ligand binding, Jones and Sharp (1997) demonstrated that JH III and JH III acid change the conformation of recombinant *D. melanogaster* USP, while farnesol and 20E do not. The USP–JH III acid interaction generates anomalous spectra, suggesting that it may not trigger a conformational change that is identical to that obtained with JH III. These investigators estimate the dissociation constant of the USP: JH III complex to be approximately 1 μM, a value considerably higher than might be expected for a nuclear receptor that must sequester hormone directly from the circulatory system. Further refinement of the original studies indicated that methoprene competes with JH III for a binding site on USP (Jones *et al.*, 2001). It should be cautioned that these studies used only partially purified (75%) racemic JH III, yet the investigators chose to express ligand concentrations as "concentrations of the natural active isomer in the respective binding reaction" (Jones *et al.*, 2001). Arbitrarily overlooking the impurities in the hormone preparation and using an estimated 10*R* JH III concentration may present problems in the interpretation of the binding constants.

Nevertheless, evidence from functional transcription assays supports this model. Using modified USP response elements coupled to a JHE core promoter (−61 to +28 relative to the start site) and a reporter gene, Jones *et al.* (2001) demonstrated that construct expression could be induced by JH III in a dose-dependent fashion. The promoter construct was only weakly responsive to all *trans*-retinoic acid and did not respond to triiodo-L-thyronine (Jones *et al.*, 2001). Functional transcriptional assays also demonstrate that point mutations in the putative JH III binding site of USP, which abolish JH binding, cause the mutant receptor to act as a dominant negative and suppress JH III activation (Xu *et al.*, 2002).

Jones *et al.* (2001) suggested that high levels of JH III induce a conformational change in structure to stabilize dimeric/oligomeric forms of USP. This interaction may be important in dimerization of USP with its ecdysteroid receptor partner, but how it occurs and the role of USP–DNA binding in stabilization of the complex is not yet understood. It is well known that ecdysteroids induce enhanced

heterodimer formation even when the binding of the heterodimers to cognate DNA response elements does not occur (Lezzi *et al*., 2002).

The initial crystallographic analyses of the USP ligand binding domains from *H. virescens* (Billas *et al*., 2001) and *D. melanogaster* (Clayton *et al*., 2001) indicated that the putative ligand binding site is locked in an antagonist conformation. More recently, Sasorith *et al*. (2002) reinvestigated the site and found that recombinant USP could bind ligands and attempted, using computer algorithms, to dock putative ligands in the binding site. Their studies indicate that the ligand binding site is relatively large and predominantly lined with hydrophobic residues. Interestingly, the binding site of the recombinant USP contains a phospholipid inserted by the expression host, and it would be of considerable interest to know how this lipid can affect JH binding.

Computation docking of JH and analogs in the binding site of recombinant *H. virescens* USP suggests that JH may fit the putative site; however, the percentage of occupancy of the ligand binding sites by these ligands lies in the bottom range of values for classical nuclear receptors, thus raising concern about the validity of USP as the juvenile hormone receptor (Sasorith *et al*., 2002).

USP, with its large ligand binding site and a low level of occupancy, behaves more like a sensor than a classical high affinity receptor. Indeed, using the sensor model (Chawla *et al*., 2001), one might envision an entirely different role for USP, based on nutritional levels in the premetamorphic larva. When sufficient levels of a key dietary lipid(s) have been attained, the USP binding site becomes saturated with that nutritional ligand, which, in turn, alters the conformation of the protein. Ligand-activated USP might then enhance ecdysteroid binding by its partner, ECR. Ligand activation of the appropriate ecdysteroid receptor isoforms leads to changes in neuronal activity (Hewes and Truman, 1994; Truman, 1996) that may trigger activity in the prothoracicotropes or dendritic fields enervating them. While this hypothesis is simplistic, it could account for the very early signaling events that initiate ecdysis. It now seems clear that USP binds JH, albeit with low affinity, as well as other lipids. It may be that refinement of experiments presented by the Jones laboratory will shed new light on how the hormone acts at the molecular level.

3.7.12.2. Juvenile Hormone Interaction with the *Methoprene-Tolerant* Gene

Using mutagenesis studies to dissect the molecular action of JH, Wilson and his group have examined a locus in *D. melanogaster*, the *Methoprene-tolerant* (*Met*) locus, that encodes for a protein similar in sequence to proteins in the basic-helix–loop–helix–PAS (bHLH-PAS) family of transcriptional regulators (Wilson and Ashok, 1998). Treating wild-type flies with high levels of methoprene at certain times during larval development leads to a distinct array of developmental abnormalities, including aberrations in the central nervous system, salivary glands, and muscles (Restifo and Wilson, 1998). In contrast to wild-types, flies carrying the *Met* mutation are resistant to high levels of methoprene and appear to develop and reproduce normally (Wilson and Fabian, 1986).

The *Met* gene (GenBank Accession no. AF034859) encodes for a 716-residue protein which in wild-type flies displays a dissociation constant of 6 nM for JH III (Shemshedini *et al*., 1990). Competitive displacement studies comparing the homologs indicate that JH I, JH II, JH III acid, and methoprene are weak competitors when compared with JH III; methoprene binding is 100-fold weaker than that of JH III. Flies carrying the *Met* mutation exhibited a significantly reduced (sixfold) binding affinity for JH III (38 nM). The reduced affinity of the 85 kDa Met protein for methoprene translates into a 50–100-fold increase in resistance to both its toxic and morphogenetic effects. Flies carrying the *Met* mutation are also resistant to toxic levels of the naturally occurring hormones JH III and JHB_3, but not to various other classes of insecticides. This important distinction demonstrates that *Met* is not a general insecticide-resistance gene, but is specific for JH and JH analogs (Wilson *et al*., 2003).

Analysis of the *Met* sequence indicates it has three regions displaying similarity to the bHLH–PAS family of transcriptional regulators. It is instructive to note that the bHLH–PAS gene family was named for three important members of the group: the *Period* gene, the *Aryl hydrocarbon receptor* gene, and the *Single-minded* gene. Of particular importance is the similarity of *Met* to the *Aryl hydrocarbon receptor* (*Ahr*) gene that encodes for a xenobiotic binding protein (Ashok *et al*., 1998). The fact that methoprene interacts with a member of the AHR family of receptors may explain why so many compounds structurally distant from JH have JH-like activity (Stahl, 1975). With its similarity to AHRs, Met could bind hydrophobic ligands that marginally resemble JH and regulate certain JH-responsive genes (Ashok *et al*., 1998). Equally interesting is the fact that the vertebrate AHR partners with another protein, the aryl hydrocarbon nuclear translocator, to form an active transcriptional regulator that activates genes responsible for mediating the

response to xenobiotics. While no partner has yet been found for Met, the potential for such an interaction has been noted (Restifo and Wilson, 1998).

Immunolocalization studies suggest that Met is limited to nuclei (Pursley *et al.*, 2000), thus ruling out the earlier suggestion that Met acts as a cytosolic "sink" (Shemshedini *et al.*, 1990). Developmentally, it is present in all cells of the *Drosophila* embryo from the 256 cell stage until early gastrulation, when the signal begins to decline. In second and third stadium larvae Met is found in salivary glands, fat body, imaginal discs, and gut primordium. *Met* is also present in pupal histoblasts and in adult reproductive tissues, including the female ovarian follicle cells and spermatheca and the male accessory glands (Pursley *et al.*, 2000).

To date, over a dozen alleles of *Met* have been recovered in genetic screens (Wilson *et al.*, 2003), but one in particular, Met^{27}, poses a perplexing question about the role of Met in JH action. When examined by Northern analysis and RT-PCR, flies homozygous for Met^{27} lack *Met* transcripts, yet these insects survive and develop into adults. The lack of *Met* expression becomes evident only in the adult female, in which there is an 80% reduction in oogenesis (Wilson and Ashok, 1998). If flies carrying a null mutation in *Met* can undergo seemingly normal development and limited oogenesis, both events being under JH control, the role of Met in JH action is open to question. Pursley *et al.* (2000) suggest that "genetic redundancy" (Krakauer and Plotkin, 2002), the equivalent of back-up systems for biological phenomena, may be involved in this situation. Given the apparent lack of Met functions during the larval stages, but its significant role in both male and female reproduction (Wilson and Ashok, 1998; Wilson *et al.*, 2003), it may be that JH utilizes several different and distinct molecular pathways to control development and reproduction.

3.7.12.3. Juvenile Hormone and Metamorphosis: The Role of the *Broad*-Complex

A growing body of evidence has implicated the transcription factor Broad (FlyBase identification no. FBgn0010011) as a key component in the initiation of metamorphosis (Riddiford *et al.*, 2003). Mutations in *Broad*, a member of the Broad-Tramtrack-Bric-a-Brac family, allow normal larval development to occur but prevent pupation (Kiss *et al.*, 1988; Bayer *et al.*, 1996; Riddiford *et al.*, 2003). Less severe Broad phenotypes have wings that are shorter and wider than wild-types. The *Broad* gene is large (100 kb) and in *Drosophila* encodes for at least six isoforms of the protein, which all share a common N-terminal of approximately 425 amino acids (Bayer *et al.*, 1996). Through alternative splicing, the C-terminal can be represented by any one of four pairs of C_2H_2-type zinc finger domains, Z1, Z2, Z3, and Z4. The N- and C-terminals are connected by linkage domains of varying lengths. The Z4 transcript encodes a protein of 877 amino acids.

After the onset of metamorphosis, the nuclei of all larval and imaginal cells display Broad; however, each tissue appears to have its own specific constellation of isoforms that appear in a temporally unique sequence (Mugat *et al.*, 2000). For example, Mugat *et al.* (2000), using an isoform-specific antibody in their studies on *D. melanogaster* fat body, followed a shift from Z2 to the other isoforms as metamorphic events proceed. Bayer *et al.* (1996) demonstrated that Z1 is the predominant isoform during pupal cuticle formation in the abdominal epidermis and imaginal discs.

Ingestion of the JH analog pyriproxifen by first instar *D. melanogaster* prolongs the third stadium by several days (Riddiford *et al.*, 2003) and results in a 12 h delay in the appearance of Broad in abdominal epidermis. By the time of pupation, however, Broad protein levels were similar to controls, indicating that this potent JH analog cannot prevent the appearance of this protein. The adult abdominal epidermis, formed from nests of tissue called histoblasts, begins to proliferate and spread over the abdomen after puparium formation. These new cells displace the existing larval cells. Broad is found in larval cells that are destined to die, but cannot be found in imaginal cells once they have spread across the abdomen. Interestingly, JH treatment delays the loss of Broad in the imaginal cells and causes these cells to produce proteins indicative of a pupal-like cuticle. Increasing Z1 levels through misexpression at the onset of adult cuticle formation mimics the effects of JH, causing the reappearance of mRNAs encoding pupal cuticular proteins and the suppression of mRNAs encoding adult cuticular proteins (Zhou and Riddiford, 2002). These investigators suggest that JH prolongs the expression of the Z1 isoform, and suppresses the onset of adult cuticular formation.

In *M. sexta*, only three Broad isoforms have been discovered, Z2, Z3, and Z4, with Z4 being most prominent in epidermal tissue involved in pupal cuticle formation (Zhou *et al.*, 1998; Zhou and Liu 2001). As observed in *D. melanogaster*, the protein's appearance is well-defined spatially and temporally, following the pattern of pupal commitment, as defined by the loss of sensitivity to JH. Most significantly, within 6 h of 20E treatment, epidermal

preparations *in vitro* display a marked rise in Broad mRNA (Zhou *et al*., 1998; Zhou and Riddiford, 2002). This rise signals the onset of commitment to pupation. In cells that are not yet committed, JH I prevents the induction of Broad mRNA synthesis by 20E (Zhou *et al*., 1998). Once Broad appears in the cells, JH can no longer suppress the accumulation of Broad mRNA, and its levels remain elevated, even during the rise in JH titers later in the stadium. *Broad* expression eventually disappears during the early pupal stage coinciding with the onset of adult cuticular synthesis. The role of Broad was further defined by applying sufficient JH to pupae to elicit the formation of a second pupal cuticle; in this case, Broad mRNA and protein rose after exposure to 20E, then dropped after the second pupal cuticle was formed (Zhou and Riddiford, 2002). Thus, Broad's presence in the cell appears to inhibit larval cuticular synthesis, while permitting pupal cuticular synthesis to proceed. Moreover, Broad appears to suppress the synthesis of the adult cuticle. Exogenous JH can delay but not prevent the expression of Broad, but the molecular actions of the hormone remain unclear.

3.7.12.4. Juvenile Hormone Regulation of Cytosolic Malate Dehydrogenase

JH has long been implicated in the regulation of cellular energy production and of biochemical and second messenger pathways. This long history includes research on such diverse mechanisms as modification of oxidative phosphorylation (Clarke and Baldwin, 1960; Chefurka, 1978); shifts in cellular potassium levels (Kroeger, 1968); membrane perturbation (Baumann, 1969; Barber *et al*., 1981); second messenger regulation (Everson and Feir, 1976; Kensler *et al*., 1978; Yamamoto *et al*., 1988); changes in cytoskeletal structure (Capella and Hartfelder, 2002); and the development of asymmetric organs (Adam *et al*., 2003). Interest in certain of these areas has been rekindled by a series of studies carried out by Farkas and his associates on the regulation of cytosolic malate dehydrogenase in *D. melanogaster* (Farkas and Knopp, 1997, 1998; Farkas and Sutakova, 2001; Farkas *et al*., 2002).

Cytosolic malate dehydrogenase (EC 1.1.1.40), also known as NADP-malic enzyme (ME), is involved in production of cytoplasmic NADPH. The enzyme is particularly prevalent in tissues that are involved in fatty acid synthesis and it is a target for various hormones in vertebrates (Farkas *et al*., 2002). In a series of papers, Farkas and his group have demonstrated that ME, a product of the *Men* gene (CG 10120; FBgn 0002719), is under the regulation of JH during the mid-third stadium of *D. melanogaster*. A dose of 5 pg of JH III will elicit half-maximal ME activity and while this level is higher than physiological levels (0.02 pg per larva) (Sliter *et al*., 1987), it is still lower than the dose typically used to induce morphological abberations (Riddiford and Ashburner, 1991).

The response to JH III occurs in two phases, an early phase occurring 3 h after treatment, in which ME activity doubles, and a late phase occurring 12 h after treatment, in which a threefold increase over the control is observed. The transcriptional inhibitor actinomycin D does not block the early ME rise, but does block the late rise, suggesting that JH can increase ME activity without new protein synthesis. That JH added directly to the cytosol can not induce the ME rise indicates that the hormone may be acting through a pre-existing pathway that is immediately affected, such as that of a second messenger cascade (Farkas *et al*., 2002). In contrast to the early rise, the late rise in ME activity is sensitive to actinomycin D, indicating that this rise is dependent on *de novo* transcription of ME. The authors have yet to examine the levels of ME mRNA that would confirm the inhibitor studies.

Using developmentally staged, wild-type larvae and the temperature-sensitive mutants ecd^{1} and $su(f)^{ts67g}$, Farkas *et al*. (2002) demonstrated that ecdysteroids are also involved in the JH-regulated ME rise. Wild-type flies respond to JH only near the time of pupariation, when ecdysteroid titers begin to rise. By contrast, in temperature-sensitive, ecdysone-deficient mutants, JH is unable to initiate the expected ME rise at elevated temperatures. These observations suggest that a complex synergistic regulatory mechanism is acting to control ME levels. A low level of ecdysteroid must be present before JH can induce activation of ME, yet high levels of ecdysteroid, such as those seen at pupariation, downregulate the activity of ME. The physiological role of JH in upregulating this event cannot be well understood unless placed in the context of lipogenesis. Farkas *et al*. (2002) suggest that the ME–JH interaction may play a role in increasing the levels of unsaturated fatty acids. JH and certain JH analogs have been shown to induce a rise in unsaturated fatty acids (Schneider *et al*., 1995) and phospholipid levels (Della-Cioppa and Engelmann, 1984) in adult *S. gregaria* and *L. maderae*. In *D. melanogaster*, the ecdysteroid-induced onset of metamorphosis leads to the cessation of feeding; it may be that high levels of JH during the earlier stadia and the early part of the last stadia ensure availability of lipid resources during metamorphosis. While the pathways are still not clear, this paradigm of JH

action at the molecular level holds much promise for better understanding how the hormone may regulate homeostatic mechanisms that are necessary for insect growth and development.

3.8 Feedback Regulation of Prothoracic Gland Activity

S Sakurai, Kanazawa University, Kanazawa, Japan

3.8.1. Introduction

The physiologic effects of insect hormones depend to a large extent on their concentration in the hemolymph. The hormone concentration exposed to target cells is determined by three factors: synthesis and secretion, the downregulation of hormone secretion, and the rates of degradation and elimination. The synthesis, secretion, and downregulation are to a great extent mediated by positive and negative feedback circuits. In the vertical sequences like the hypothalamic–pituitary–thyroid axis of adult vertebrates for example, thyroid hormone suppresses the synthesis and release of thyrotropin releasing hormone (TRH) from neurosecretory cells (NSCs) in the paraventricular nucleus of the hypothalamus as well as thyroid stimulating hormone (TSH) from the thyrotrophs in the adenohypophysis. The control of hypothalamic TRH release by thyroid hormone is referred to as long-loop feedback, and that of TSH release from the pituitary gland as short-loop feedback, while the control of the thyroid gland itself by thyroid hormone is called ultra-short-loop feedback. The definition of feedback is, however, rather vague among insect endocrinologists and the term "feedback" has been used occasionally to denote a "horizontal" connection between two or more secretory organs, i.e., the reciprocal interaction between the prothoracic gland and corpus allatum, although these organs are not organized vertically. In the present chapter, the term feedback indicates both feedback in the vertical sequences and horizontal connections, thus covering an intricate network. In addition, the terms, long-loop, short-loop, and ultra-short-loop will not be used, those being simply denoted as feedback unless otherwise indicated.

The endocrine control in insects governs diverse biological events in gamete formation, embryonic development, postembryonic development, homeostasis, and behavior, many of which are believed to be under the control, directly or indirectly, of neuropeptides, and therefore neurosecretion. The insect endocrine system is significantly neuroendocrine, as nearly 17% of the cells of the central nervous system (CNS) produce neuropeptides (Gäde *et al.*, 1997; Predel and Eckert, 2000) (see **Chapter 3.10**). Although each ganglion in the CNS contains a number of NSCs with different characteristics with regard to

both size and developmental changes in their shapes and content, only a few NSCs have been characterized on the basis of their product. Even in the secretory cells whose products have been identified and their roles established, very little is known about the feedback regulation of cell activity.

In insects, a few endocrine glands are part of the peripheral secretory organ system. These are the prothoracic gland that secretes ecdysone (see **Chapter 3.3**), the corpus allatum that secretes juvenile hormone (JH) and functions as a neurohemal organ for various neuropeptides produced by the brain NSCs (see **Chapter 3.7**), the corpus cardiacum that secretes peptide hormones involved in the control of energy metabolism (Gäde *et al.*, 1997), the epitracheal gland that includes the Inka cell that releases ecdysis triggering hormone (Zitnan *et al.*, 1996) (see **Chapter 3.1**), the ovary and testes, both of which are known to produce ecdysone in a distinct period of the insect life cycle (Hagedorn *et al.*, 1975; Lagueux *et al.*, 1977; Hetru *et al.*, 1978; Delbecque *et al.*, 1990) (see **Chapter 3.9**), the gut that contains a number of myotropic factors (Gäde *et al.*, 1997) (see **Chapter 4.5**), epidermal cells, a source of dopamine (Noguchi and Hayakawa, 1996) and ecdysone in the argasid tick (Zhu *et al.*, 1991) (see **Chapter 3.16**), and the fat body secreting an insect cytokine, growth-blocking peptide (Hayakawa *et al.*, 1998) and growth factors, one of which is imaginal disc growth factor (IDGF) known to stimulate cell proliferation of wing imaginal discs in *Drosophila* (Kawamura *et al.*, 1999). Among those peripheral glands, feedback regulation is known only in the axis of the brain–Inka cell at ecdysis (see **Chapter 3.1**) and the brain–prothoracic gland axis (see **Chapter 3.2**). No information is available on the feedback regulation of the production and/or secretion of metabolic hormones such as hypertrehalosemic hormone and adipokinetic hormone from the corpora cardiaca (see **Chapter 3.10**), although they are crucially involved in the homeostasis of blood sugars and lipids, and even of allatotropin and allatostatin that control JH secretion from the corpora allata (see **Chapter 3.7**).

In addition to feedback in the vertical axis, horizontal interactions are known between the prothoracic glands and corpora allata. Ecdysteroids and JHs interact, and we cannot study one without considering the other (Gilbert *et al.*, 2000). Thus, the feedback regulation of the brain–prothoracic gland axis and the horizontal controls involved in ecdysteroidogenesis will be the main focus of this chapter (**Figure 1**).

3.8.2. Feedback Regulation of Brain–Prothoracic Gland Axis

3.8.2.1. Feedback Regulation of Brain Neurosecretory Cells by 20-Hydroxyecdysone

20-Hydroxyecdysone (20E) has been considered to be involved in the regulation of production and/or secretion of neurosecretory materials from brain NSCs based on the changes in NSC shape and stain intensity (e.g., Steel and Harmsen, 1971; Steel, 1975; Agui and Hiruma, 1977a, 1977b; Khalil *et al.*, 1988) (see **Chapter 3.11**), but the evidence is only circumstantial. The weakest point of those earlier studies is the lack of knowledge of the products of the NSCs in question. Most of these studies were concerned with the four pairs of large NSCs in the pars intercerebralis of the brain, which were once believed to be prothoracicotropic hormone (PTTH) cells (Steel and Harmsen, 1971; Steel, 1975; Agui and Hiruma, 1977a) but are not now believed to be so (Agui *et al.*, 1979; Mizoguchi *et al.*, 1990; Gilbert *et al.*, 2000). This indicates that ecdysteroids affect other NSCs besides the PTTH cells, although it is not truly feedback regulation. It should be noted that the nomenclature of negative and positive feedback in the earlier literatures is somewhat confusing. When 20E injections increase the stain intensity of NSCs, this was described as a positive feedback effect, although it is not certain whether the increase in stain intensity is a result of feedback inhibition of neurosecretion or activation of the gene encoding the neuropeptide or both. Both *in vivo* and *in vitro* experiments show that 20E elicits an increase in the stain intensity of most brain NSCs in *Rhodnius prolixus* (Steel, 1975) and *Mamestra brassicae* (Agui and Hiruma, 1977a). Removal of the prothoracic glands from *M. brassicae* larvae decreases the stain intensity and 20E injection recovers it (Agui and Hiruma, 1977b). Since the increased stain intensity may be caused by an increased production of neurosecretory materials or suppression of their release, or both, the results indicate that 20E stimulates the production of neurosecretory material (positive feedback) but suppresses its release (negative feedback) (Steel, 1975). The observations in those reports have been focused on the median NSCs, of which four pairs of the large cells are now believed to be bombyxin cells (Mizoguchi *et al.*, 1987; Iwami *et al.*, 1990; Moto *et al.*, 1999) (see **Chapter 3.2**), suggesting that 20E affects bombyxin secretion and/or its production. In Inka cells, that produce a peptide hormone, ecdysis triggering hormone (ETH), rising ecdysteroid levels upregulate ETH gene

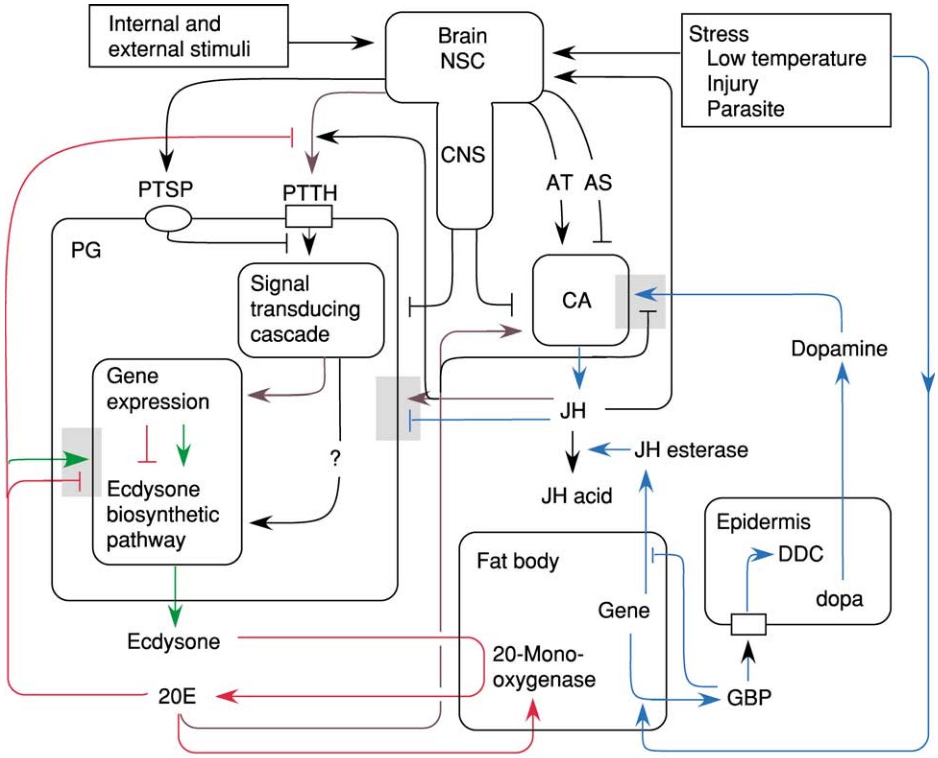

Figure 1 Vertical sequence and horizontal network of regulation of prothoracic gland, based on the information obtained mainly from studies on *Manduca sexta* and *Bombyx mori* except for the growth-blocking peptide (GBP) network. Red lines indicate the vertical sequence that provides the feedback inhibition of the brain–prothoracic gland axis. Green lines indicate partly the feedback stimulation loop. Blue lines show the horizontal regulation of the prothoracic glands through the stress–GBP network (partly hypothetical). Arrowheads and ⊥ symbols indicate stimulatory and inhibitory regulation, respectively. Shadowed area indicates that the feedback effects change along with postembryonic development: 20E inhibits the larval glands with moderate to high secretory activity, while stimulating the glands with low secretory activity as seen in early fifth instar larvae, the first day of nondiapausing pupae, and diapausing pupae of *M. sexta*. JH suppresses prothoracic glands before the onset of wandering, but stimulates the glands in the early pupal period. In the stress–GBP pathway, dopamine suppresses the corpus allatum until the middle of the fifth instar but not thereafter, probably due to the change in the type of dopamine receptor (Granger *et al.*, 1996) (see **Chapter 3.7**). AS, allatostatin; AT, allatotropin; CA, corpus allatum; CNS, central nervous system; DDC, DOPA decarboxylase; GBP, growth-blocking peptide; NSC, neurosecretory cell; PG, prothoracic gland cell; PTSP, prothoracicostatic peptide; PTTH, prothoracicotropic hormone. See text for details.

expression, while the subsequent ecdysteroid decline triggers ETH release (Zitnan *et al.*, 1999) (see **Chapter 3.1**). Although Inka cells are not NSCs, neuropeptide gene expression could be similarly upregulated in the brain NSCs, which is in accordance with the earlier observations described above.

3.8.2.2. Feedback Regulation of PTTH Cells by 20-Hydroxyecdysone

There is no firm evidence to show the feedback regulation of PTTH production and its release, but 20E appears to elicit feedback control on PTTH cells, as seen in the diapausing pupal brain of *M. brassicae* (Agui and Hiruma, 1977a) (see **Chapter 3.12**). Diapausing pupal brains were incubated with 20E for 2 days followed by incubation in fresh medium for another 2 days, and then inactive diapausing pupal prothoracic glands were placed in the latter conditioned medium. When ecdysteroid activity in the final medium was assessed biologically by adding a piece of integument, apolysis (secretion of new cuticles from the underlying epidermal cells) was induced, indicating that the conditioned medium in which prothoracic glands from diapausing pupae had been added did contain ecdysteroids. This suggested that the 20E in the first medium might have caused the brain to release PTTH. They also showed increases in the stain intensity of all median and posterior brain NSCs, but not in the lateral NSCs. The intensity of the latter actually decreased after incubation of the brain with 20E for 2 days, but it is not obvious whether these lateral NSCs are the PTTH cells that have been described as

being in the lateral region of other Lepidoptera (Agui *et al*., 1979; Mizoguchi *et al*., 1990; Gilbert *et al*., 2000) (see **Chapter 3.2**) since there are at least three types of NSCs of similar size in the lateral region. Nevertheless, the data suggest that 20E stimulates PTTH release at a moderate concentration while suppressing its release at a high concentration (Agui and Hiruma, 1977a).

Circumstantial evidence for the above hypothesis also comes from comparing the changes in hemolymph ecdysteroid and PTTH concentrations in the fourth and fifth larval instars and the pupal period of *Bombyx mori* (Mizoguchi *et al*., 2001, 2002). In the fourth instar, the PTTH titer begins to decline as the ecdysteroid titer peaks. Brain extirpation or neck ligation has been utilized to estimate the time after which the brain is not required for inducing the following larval ecdysis, referred to as the critical period, and thereby the time when sufficient PTTH is secreted (Truman, 1972). This time is approximately 14 h prior to the peak of the ecdysteroid titer in *Manduca* (Bollenbacher *et al*., 1987) and 12 h in *Bombyx* fourth instar larvae (Sakurai, 1983). This time is well correlated with the change in PTTH titer. Nevertheless, the question remains concerning the extremely low PTTH titer as low as 18 pg ml^{-1} hemolymph in *Bombyx* (Mizoguchi *et al*., 2001), which is an order of magnitude lower than the critical concentration (0.2–0.3 ng ml^{-1}) to stimulate the prothoracic glands *in vitro* (Kataoka *et al*., 1987; Kiriishi *et al*., 1992; Hua *et al*., 1999). Accordingly, it is not conclusive at present if the measured PTTH titer in the fourth instar larvae reflects the actual PTTH concentration or if there are other factors involved in the upregulation of prothoracic gland activity, although brain extracts effectively induce a larval–larval molt in neck ligated larvae (Suzuki and Ishizaki, 1986). In *Manduca*, PTTH titers in the fourth instar larval hemolymph were measured by an indirect bioassay method using paired prothoracic glands (Bollenbacher *et al*., 1987). The peak titer of PTTH was found to be 0.2 units of PTTH, just enough to activate the glands, and occurred 9 h prior to the ecdysteroid peak (Bollenbacher *et al*., 1987). When the ecdysteroid titer peaks, the PTTH titer has decreased, indicating the feedback inhibition of PTTH synthesis and/or release by 20E. At that stage any ecdysone formed would be promptly converted to 20E (Kamimura and Kiuchi, 2002). In the fifth instar, the PTTH titer declines sharply in concurrence with the beginning of the increase in ecdysteroid titer approximately 12 h later (Mizoguchi *et al*., 2002). This supports the idea of feedback inhibition of PTTH release by high ecdysteroid titers. A similar observation was made for the pupal period (Mizoguchi *et al*., 2002). In *Bombyx* pupae, the PTTH titer peaks on day 1.25 and declines after considerable fluctuations. The peak ecdysteroid titer occurs 1 day later, although both peaks are broad and overlap. The ecdysteroid titer was measured by radioimmunoassay (RIA) of crude extracts of hemolymph and the changes in individual ecdysteroids were determined by a combination of high-performance liquid chromatography (HPLC) separation and RIA measurement, a paradigm that showed that the 20E peak follows the ecdysone peak by 3 days in *Manduca* (Warren and Gilbert, 1986). Taking into consideration that pupal–adult development takes 9 days in *Bombyx,* which was the object of the studies by Mizoguchi *et al.* (2001), while the comparable period in *Manduca* is about 20 days, the 20E peak in *Bombyx* pupae should appear at least 1 day after the measured ecdysteroid peak. In that case, the PTTH titer would decline when the 20E titer has peaked. Accordingly, 20E may downregulate PTTH secretion and/or synthesis throughout the postembryonic development, except in the case of diapausing animals.

It has not been shown unequivocally that 20E exerts feedback regulation on PTTH production. At each of the developmental stages of *Bombyx*, a high ecdysteroid titer does not elicit an accumulation of PTTH in the brain (Mizoguchi *et al*., 2001) nor in the PTTH cell axon ending of the corpus allatum of *Manduca* (Dai *et al*., 1995), a neurohemal organ for PTTH, in contrast to brain NSCs indicated by the above-mentioned earlier observations (Steel, 1975; Agui and Hiruma, 1977a). It is conceivable that once 20E elicits its inhibitory effects on the PTTH cells at its high concentration at the end of the fourth and fifth instars, 20E may not only suppress PTTH secretion but also downregulate the PTTH gene. In the hypothalamic–pituitary–adrenal or –thyroid axes in vertebrates, corticosteroid or thyroid hormone downregulates the genes of tropic components in the hypothalamic NSCs and pituitary cells. The hypothalamic TRH and pituitary TSH subunit genes are downregulated by the active form of thyroid hormone, triiodothyronine (T3) (Shibusawa *et al*., 2003). There is no indication if such is also the case in PTTH gene regulation, since we know nothing about this gene, but 20E could exert its effect by downregulating the PTTH gene. Another interpretation is suggested by the study of deiodinase activity in the thyrotrophs of the anterior pituitary gland (Huang *et al*., 2001; Schneider *et al*., 2001). When TSH genes are suppressed strongly by thyroid hormone, type II iodothyronine deiodinase (D2) activity

increases in the thyrotrophs to promote the conversion of T4 to T3, the latter being stronger in its ability to bind to the thyroid hormone receptor and thereby promote binding to *trans*-regulatory elements of the TRH and TSH genes (Shibusawa *et al*., 2003). Such locally synthesized T3 acts as a negative feedback factor in suppressing the TSH gene, and therefore the localized upregulation of D2 activity may be the first step in the negative feedback loop (Huang *et al*., 2001). Although it is not known if circulating 20E in insect hemolymph is positively released from the midgut and fat body, major tissues expressing 20-monooxygenase activity (Smith *et al*., 1983), i.e., the enzyme that mediates the conversion of ecdysone to 20E, or only leaks from peripheral tissues. It might be of interest to measure this enzyme activity in PTTH cells when they are presumably negatively controlled by 20E. If the 20-monooxygenase is upregulated locally in the PTTH cells, feedback inhibition of the PTTH gene may occur earlier than the time when a 20E increase occurs in the hemolymph. Since the gene encoding the 20-monooxygenase is now known (see **Chapter 3.3**), one could use *in situ* hybridization studies to quantify that gene's transcripts in the PTTH cells.

In addition to PTTH, prothoracicostatic peptide (PTSP) appears to be present in *Bombyx* fifth instar larvae, although it is identical to the *Manduca* myoinhibitory peptide (Mas-MIP I) (Hua *et al*., 1999). PTSP does not alter the basal secretory activity of prothoracic glands *in vitro* but suppresses the PTTH-stimulated glands, presumably by inhibiting PTTH action (Hua *et al*., 1999) by blocking the calcium channel that is tightly associated with the earliest step of the PTTH signaling pathway (Dedos and Birkenbeil, 2003). PTSP has been isolated from the *Bombyx* brain, and therefore the site of synthesis is probably in the brain, but nothing is known about the location of the PTSP cells or the effects of 20E on its production and/or secretion.

3.8.3. Feedback Regulation of the Prothoracic Gland by Ecdysteroid

A decrease in the hemolymph ecdysteroid titer may be as important as its increase in various aspects of insect development. At the larval–larval molt, the DOPA decarboxylase (DDC) gene in the epidermal cells is activated in response to a decreasing ecdysteroid titer (Hiruma *et al*., 1995). DDC mediates the conversion of DOPA to dopamine, a precursor of DOPA quinone that mediates sclerotization by chemically bridging cuticular proteins (see **Chapters 4.2** and **4.4**) and which also serves as an intermediate in melanin production for melanization. Therefore, an artificial increase in ecdysteroid concentration delays the melanization process. Similarly, adult eclosion is delayed by 20E injection (see **Chapter 3.1**). In spite of the recognition of the importance of feedback regulation of prothoracic gland secretory activity, only six papers on this subject have been published in the last 50 years (Williams, 1952; Siew and Gilbert, 1971; Beydon and Lafont, 1983; Bodnaryk, 1986; Sakurai and Williams, 1989; Song and Gilbert, 1998; review: Gilbert *et al*., 1997). The next section is based on those publications.

3.8.3.1. Feedback Activation of Ecdysteroid Production

The first paper that indicated the feedback activation of prothoracic glands appeared in 1952, although the term "feedback" was not used. Rather, it was stated that "prothoracic glands can be triggered also by the prothoracic gland hormone itself" in the famous experiments involving the parabiosis of eight brainless diapausing pupae and chained pupal abdomens of *Hyalophora cecropia* (Williams, 1952). This study doubtlessly describes the positive feedback regulation of prothoracic gland activity. There are three reports to support feedback activation in *Manduca* (Sakurai and Williams, 1989), the bertha armyworm *Mamestra configurata* (Bodnaryk, 1986), and *Bombyx* (Sakurai and Imokawa, 1988) although Bodnaryk does not mention positive feedback. The prothoracic glands of day 2 fifth instar *Manduca* larvae were inserted into diapausing pupae that had had their brains removed, and gland activity was then measured *in vitro* every day after implantation. In such pupal preparations, the implants exhibited periodic changes in secretory activity, as the peaks of 50–60 ng per gland appeared 4, 7, and 12 days after the implantation. Each peak was separated by a nadir of activity of approximately 20 ng per gland. The same was also the case in pupal preparations lacking both brain and prothoracic glands. The implanted day 2 glands may be stimulated by ecdysteroid they synthesize. When the activity attains a considerably higher level than a threshold in the host pupae, the glands are inhibited. Once the gland activity decreases to a low level, they are again capable of being activated by their ecdysteroids or those of the host prothoracic glands that may have been activated by the ecdysteroid produced by the implanted glands. These *in vivo* observations indicate the presence of feedback activation. However, the glands of feeding larvae are barely activated by either ecdysone or 20E *in vitro*. By contrast, *in vitro* administration of 20E stimulates diapausing pupal

glands as well as day 1 nondiapausing pupal glands (Sakurai and Williams, 1989). A similar autonomous change in the gland activity is observed in *Bombyx* fifth instar larvae (Sakurai and Imokawa, 1988). Larvae lacking the retrocerebral complex (brain–corpora cardiaca–corpora allata) are capable of gut purge followed by pupation if the surgical operation was done on day 4 of the instar, 2 to 3 days before gut purge. After the operation, the gland activity gradually increases and gut purge is induced. Subsequently, the activity sharply decreases to its lowest level before pupation. Although *in vitro* challenge by ecdysteroids failed to activate glands of feeding *Manduca* larvae, the composite data indicate that 20E causes stimulation of ecdysteroid production of glands when their secretory activity is as low as those of diapausing pupae, but the feedback activation of young last instar larval glands of relatively low secretory activity is conjectural.

In *M. configurata* pupae, injection of 20E (500 ng g^{-1} fresh weight) into postdiapause, pupae 1 day after transfer to 20 °C from 6 to 8 months of storage at 0 °C accelerates the increase in ecdysone concentration in the hemolymph in about 1 day and in the 20E concentration in about 2 days. In contrast, a higher 20E dose, as much as 2500 ng g^{-1}, suppressed the occurrence of both ecdysteroid peaks (Bodnaryk, 1986), as will be discussed below (see Section 3.8.3.2). In postdiapause pupae, ecdysone and 20E titers begin to increase 4 and 7 days after being transferred to 20 °C, showing that the glands 1 day after the transfer are apparently not yet activated, and therefore, indicates that the exogenous 20E stimulated the glands having very low or no secretory activity, as in the *H. cecropia* and *Manduca* diapausing pupal glands.

In diapausing pupae, either photoperiod induced or artificially induced by brain removal from nondiapausing pupae at pupation, adult development initiates spontaneously if it is not a deep diapause, as for the univoltine *H. cecropia*. In brainless pupae, there is no PTTH source, but in such *Manduca* pupae, ecdysone is the major ecdysteroid and [^{3}H]-cholesterol is incorporated into ecdysone at the beginning of spontaneous adult development, indicating that the prothoracic glands were activated in those pseudodiapausing pupae (Sakurai *et al.*, 1991). Since they lack a brain, the prothoracic glands may be activated by signals other than PTTH, possibly by the positive feedback of ecdysteroid that the prothoracic glands secreted. Although feedback activation has been recorded for pupal prothoracic glands, there is no evidence that such activation is responsible for the increase in ecdysteroid titer that triggers pupal–adult development.

3.8.3.2. Feedback Inhibition

Siew and Gilbert (1971) first showed the negative feedback regulation of prothoracic gland activity. This is more easily explainable than that discussed above, i.e., to downregulate the glands once they have secreted enough ecdysteroid to initiate the molting process. Later, feedback inhibition of the prothoracic glands was described in the large cabbage butterfly *Pieris brassicae* (Beydon and Lafont, 1983), *M. configurata* (Bodnaryk, 1986), and *M. sexta* (Sakurai and Williams, 1989; Song and Gilbert, 1998). In *Pieris* pupae, the inhibition of ecdysteroid biosynthesis by exogenous 20E is dose dependent (Beydon and Lafont, 1983). In *Manduca*, when prothoracic glands at peak activity 2 days after the onset of wandering were implanted into pupae from which the brain–corpora cardiaca–corpora allata complex and prothoracic glands had been removed, the 3-dehydroecdysone (see **Chapter 3.3**) secretory activity of the implanted glands decreased at the same rate as those in intact larvae. Similar inhibition is elicited by 20E *in vitro*, indicating that feedback inhibition solely accounts for the decrease of secretory activity after the peak of activity that occurs prior to pupation (Sakurai and Williams, 1989).

Feedback inhibition by 20E was demonstrated clearly using the prothoracic glands of day 5 *Manduca* larvae (Song and Gilbert, 1998). The glands were incubated in the presence or absence of 20E for various time periods and then incubated in medium alone for a further 1 h to assess the basal secretory activity (**Figure 2**). The basal level of ecdysteroid production was markedly inhibited by the 1 h incubation with 20E to approximately 25% of the control. When these glands were challenged with PTTH after exposure to 20E for 24 h, the enhanced level of ecdysteroidogenesis was far less than that of the control glands. Comparison of basal ecdysteroidogenesis with PTTH-stimulated activity after gland incubation for 6 h with 20E, showed that the glands were still capable of responding to PTTH, although the basal level was very low due to the inhibition by 20E. By contrast, after 24 h incubation in medium alone, the activation ratio (amount of ecdysteroids produced by one of a paired set of glands incubated with PTTH/amount of ecdysteroids produced by the contralateral gland incubated in medium alone) (Agui *et al.*, 1979) was 11 while it was 2.5 after the incubation with 20E. In addition, the basal secretory activity after the incubation with 20E for 6 h was similar to that after incubation in medium alone for 24 h, but the activation ratio for the former glands was 4.5 whereas that for the latter glands

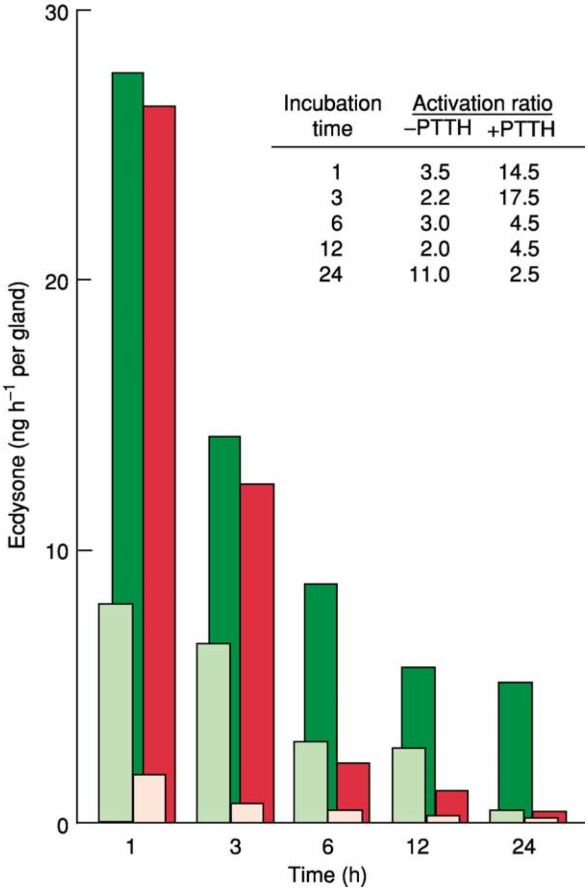

Figure 2 Inhibition by 20E of basal secretory activity and the responsiveness to PTTH of the prothoracic glands. One of a paired prothoracic glands of day 5 fifth instar *Manduca* larvae were incubated with 10 μM 20E (red and pink bars) or in medium alone (green and light green bars) for an indicated period and then incubated for another 1 h in a medium containing PTTH (red and green) or in medium alone (light green and pink) for assessing the basal secretory activity and the gland responsiveness to PTTH. Inset table: activation ratio (amount of ecdysteroids produced in the presence of PTTH/amount of ecdysteroids produced in medium alone) calculated from the paired values in the figure. Note that 20E suppresses the basal secretory activity at 1 h of incubation with 20E (light green vs. pink), while hardly affecting the PTTH-stimulated secretory activity (green vs. red). The latter is suppressed by a 6 h incubation with 20E. (Modified from Song, Q., Gilbert, L.I., **1998**. Alterations in ultraspiracle (USP) content and phosphorylation state accompany feedback regulation of ecdysone synthesis in the insect prothoracic gland. *Insect Biochem. Mol. Biol. 28*, 849–860.)

was 11, indicating that the 6 h incubation with 20E partially suppressed the gland responsiveness to PTTH. Thus, the prothoracic glands retained their competence to PTTH after a short incubation with 20E, suggesting that 20E simply suppressed the ecdysteroidogenic machinery, and that an exposure to 20E for a considerably longer period inhibited PTTH-stimulated ecdysteroidogenesis as well.

Feedback inhibition is known in crustaceans (see **Chapter 3.16**). The secretory activity of the Y-organs of the crayfish *Orconectes limosus* was greatly inhibited within 1 h after a single injection of 20E and slightly, but significantly, by a 1 h incubation with an ecdysteroid antagonist, RH-5849 (Dell *et al.*, 1999). This result is very similar to the *in vitro* feedback inhibition of *Manduca* prothoracic glands. They were markedly inhibited within 1 h by incubation with 20E (Song and Gilbert, 1998) or RH-5849 (Sakurai and Gilbert, unpublished data). Therefore, the feedback inhibition of the ecdysteroidogenic organs could be common to arthropods.

Ecdysone exerts feedback inhibition of *Manduca* day 3 fifth instar prothoracic glands *in vitro*, although the effect is faint (Sakurai and Williams, 1989). When the *Manduca* glands were inhibited by ecdysteroids (see Section 3.8.5.1), USP-1 and USP-2 proteins appeared in complementary patterns with USP-2 being predominant (see **Chapter 3.5**). Both suppression of USP-1 protein synthesis and simultaneous up-regulation of USP-2 synthesis are brought about by ecdysone and 20E. The effective concentration of ecdysone is, however, 100-fold as much as 20E (Song and Gilbert, 1998). This weak effect of ecdysone is consistent with the K_d of ecdysone for the nuclear receptor complex, which is lower than that of 20E by a factor of more than 100 (Cherbas *et al.*, 1980) (see **Chapters 3.5** and **3.6**). Since the prothoracic glands express no 20-monooxygenase activity mediating the conversion of ecdysone to 20E (Warren *et al.*, 1988), the result still indicates a weak action of ecdysone. Although ecdysone metabolites have been proposed to have morphogenetic roles of their own (Gilbert *et al.*, 2000; Gilbert, personal communication), no information is available on the possibility that 20,26-dihydroxyecdysone, the immediate metabolite of 20E, exerts feedback inhibition on prothoracic glands.

3.8.3.3. Complete and Incomplete Inactivation

There are two types of suppression of prothoracic gland secretory activity. One is incomplete shutdown, as seen at the ecdysis from the third (second penultimate) to the fourth (penultimate) instar and also at the end of the fifth (last) instar associated with the climax of pupal metamorphosis. In those periods, the gland activity declines greatly but still remains at a low level as the glands are still capable of secreting considerable amounts of ecdysone when examined *in vitro* (Okuda *et al.*, 1985; Bollenbacher *et al.*, 1987). In addition, they retain competence to respond to PTTH (Okuda *et al.*, 1985; Gu *et al.*, 2000; Takaki and Sakurai, 2003). By contrast, at the time of ecdysis from the penultimate to the last larval instar in *Bombyx*, gland activity is completely shut down for a period of 2–3 days (Okuda *et al.*,

1985; Gu *et al.*, 1997). In *Manduca*, the *in vitro* secretory activity of the glands on the second day of the fifth instar is 0.01–0.03 ng h^{-1} per gland (Smith and Pasquarello, 1989; Rybczynski and Gilbert, 1994) (see **Chapter 3.2**), indicating that activity is at an almost negligible level. In this stage in *Bombyx*, the glands are insensitive to PTTH. It is not clear if this insensitivity is due to the disappearance of the PTTH receptor from the gland cell membranes or a deficiency of one or more factors involved in the PTTH signaling. Whatever the cause, JH is involved in maintaining this inactivity. When the corpora allata are removed from newly molted *Bombyx* fifth instar larvae, the basal secretory activity of their glands reappears 9 h after the allatectomy. Three hours before this time, the glands exhibit a normal response to PTTH (Sakurai *et al.*, 1989a). This indicates that all the apparatus for ecdysteroidogenesis has been recovered before initiating spontaneous ecdysone secretion, and JH acts to maintain the suppressed condition (Takaki and Sakurai, 2003). Thus, feedback inhibition late in the penultimate instar may affect some steps of ecdysteroidogenesis and such a deficiency is maintained by JH. However, there is no information about whether the PTTH receptor itself has disappeared, either due to repression of its gene expression or it is simply sequestered away by the involution of the plasma membrane into the inside of the cells. Because dibutyryl cAMP and IBMX, a phosphodiesterase inhibitor, have lost their ability to enhance ecdysteroidogenesis at this stage (Gu *et al.*, 2000; Takaki and Sakurai, 2003), a simple deficiency of PTTH receptors can hardly account for the gland's inactivity.

3.8.4. Mechanisms of Decrease in Hemolymph Ecdysteroid Titer: Biochemical Aspects

3.8.4.1. Inactivation of 20-Hydroxyecdysone

There are at least two possible reasons for the decrease in the hormone titer, i.e., an increase in inactivation and excretion, and/or a decrease in hormone production. When ecdysone is injected into the body cavity of either a fifth (last) instar larvae or adult of *Locusta migratoria*, the ecdysteroid concentration at first increases, but promptly declines (Hoffmann *et al.*, 1974). The fate of the injected ecdysone is stage specific. On day 7 of the 11 day long instar when the hemolymph ecdysteroid titer is at its highest, ecdysone is promptly converted to 20E within 2 h and then is slowly excreted with the feces. In contrast, in either early or late fifth instar larvae or adults, the injected ecdysone is excreted promptly into the feces as is, or after conversion to inactivation products. This indicates that at the time of peak ecdysteroid titer, feedback inhibition by 20E may act to increase the excretion process, since at this time, 20-monooxygenase activity is maximal while the excretion rate is at its lowest. This results in the accumulation of 20E in the hemolymph.

In the metabolism of ecdysteroids, there are two immediate inactivation steps, epimerization and hydroxylation (see **Chapter 3.3**). Epimerization occurs at C3 to form 3-epiecdysteroid via an intermediate, 3-dehydroecdysteroid (Webb *et al.*, 1995). Since the hemolymph contains a high level 3-dehydroecdysone 3β-reductase activity (Sakurai *et al.*, 1989b; Kiriishi *et al.*, 1990), it is not possible to reduce 3-dehydroecdysteroid to 3-epiecdysteroid in hemolymph by the 3α-ketoreductase. Accordingly, inactivation of ecdysteroid through 3-epimerization is restricted only to tissues. Another immediate inactivation reaction of 20E, and probably the most important for 20E metabolism, is brought about by hydroxylation at the terminal carbon of the side chain to form 20,26-dihydroxyecdysone. This is further oxidized to the 26-oic acid and exhibits no biological activity. In the midgut cytosolic fraction prepared from feeding larvae of *Manduca*, the 26-hydroxylase is induced by 20E through the upregulation of its gene (Williams *et al.*, 1997). Although we have no information on 20,26-dihydroxyecdysone concentrations in larval hemolymph, it is highly possible that it achieves a maximum following that of 20E, similar to what occurs in *Manduca* pharate adults. Since the 26-hydroxylase is induced by 20E during the larval period, it would be of interest to examine the feedback effects of 20,26-dihydroxyecdysone on ecdysteroidogenesis. In *Manduca* pharate adults, the 20,26-dihydroxyecdysone concentration increases after the peak in the 20E titer, and becomes the sole free ecdysteroid metabolite among the various radioimmunoreactive steroids in the hemolymph at this stage (Warren and Gilbert, 1986). Accordingly, the upregulation of the 26-hydroxylase gene by 20E may be the ultimate cause of the decrease in the hemolymph 20E titer during the pupal–adult development. However, this may not be the sole reason for the decrease in 20E titer, since at this period, ecdysone secretion has almost ceased due to the degeneration of prothoracic glands, the result of programmed cell death induced by 20E (Dai and Gilbert, 1997, 1998).

3.8.4.2. Suppression of Ecdysteroidogenesis

There may be at least three different targets for the negative feedback induced by 20E in prothoracic gland cells: the enzymes of the ecdysone biosynthetic

pathway, the hypothetical system for the subcellular movement of intermediary ecdysteroid metabolites, and the signaling pathway for PTTH (**Figure 3**). Ecdysone synthesis is a complicated pathway and our knowledge is still rudimentary. We have extensive knowledge of only some of the steps occurring in the prothoracic glands (Gilbert *et al.*, 2002) (see **Chapter 3.3**). The first reaction is the dehydrogenation of cholesterol to 7-dehydrocholesterol by a P450 (CYP) enzyme in the endoplasmic reticulum (ER) (Grieneisen *et al.*, 1993; Warren and Gilbert, 1996). It is followed by a series of complex and uncharacterized oxidation reactions occurring in a location that is presently unknown, although it has long been thought to be the mitochondria in analogy with mammalian steroidogenesis (see below). The product of these reactions, an ecdysteroid precursor, is then hydroxylated at C25 by another CYP enzyme present in the ER (Kappler *et al.*, 1988), followed by additional hydroxylations at C22 and finally C2, both catalyzed by different CYP enzymes present in the mitochondria (Warren *et al.*, 2002) (see **Chapter 3.3**). The product, either 3DE and/or E (Warren *et al.*, 1988), is then secreted from the prothoracic gland cell by another unknown process and subsequently is taken up into peripheral tissues and converted to 20E by ecdysone-20-monooxygenase, another CYP enzyme variously localized in both the ER and mitochondria (Petryk *et al.*, 2003). 20E possibly affects one or more of these enzymes involved in the biosynthesis of ecdysone, but the effects of 20E on P450 activities have not yet been investigated.

Involvement of both the ER and mitochondria in ecdysone biosynthesis indicates that both cholesterol and ecdysone precursors must necessarily be conveyed between critical subcellular domains, including but not limited to the ER and the mitochondria, during ecdysone biosynthesis. Some of

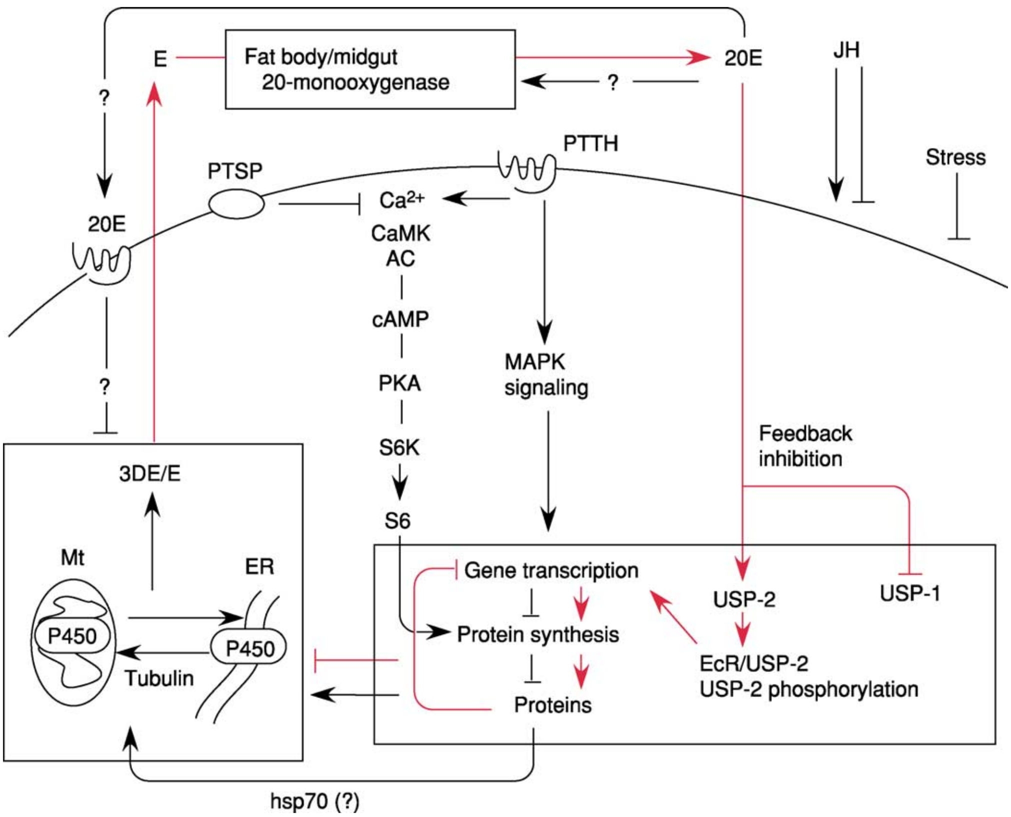

Figure 3 Feedback regulation of ecdysteroidogenesis in the prothoracic gland cell. Red lines indicate the ultra-short-loop feedback inhibition, which has been so far revealed. Arrowheads and ⊥ symbols indicate activation and inhibition, respectively. Note that 20E binds to USP-2 and activates EcR/USP-2 though the responsible isoform of EcR has not yet been identified. Then the nuclear receptor heterodimer acts as a transcription activator and the resulting proteins may suppress the genes whose products are involved in ecdysteroidogenesis (Song and Gilbert, 1998). See **Chapter 3.2**; for details of the PTTH signaling pathway and see **Chapter 3.3** for the ecdysone synthesis pathway. The membrane receptor for 20E is hypothetical. AC, adenylyl cyclase; cAMP, cyclic AMP; CaMK, Ca^{2+}/calmodulin-dependent protein kinase; 3DE, 3-dehydroecdysone; E, ecdysone; ER, endoplasmic reticulum; MAPK, mitogen activated protein kinase; MT, mitochondrion; PKA, cAMP-dependent protein kinase; PTSP, prothoracicostatic peptide; PTTH, prothoracicotropic hormone; S6, ribosomal protein S6; S6K, S6 kinase.

these sterol translocations may be rate limiting in *Manduca* and *Drosophila* ecdysone synthesis (Warren and Gilbert, 1996; Watson *et al*., 1996), and therefore, a possible target of negative feedback regulation. In mammalian steroidogenic cells, the primary substrate, cholesterol, is transported from its intracellular reservoirs, the cell membrane and/or the ER, first to the outer mitochondrial membrane and then to the CYP enzyme present in the inner mitochondrial membrane (P450ssc), perhaps with the aid of the cytoskeleton and/or various "translocation" factors, and these processes are accelerated upon stimulation by a tropic hormone (Hall, 1995, 1997). In *Manduca* prothoracic glands, PTTH stimulates the synthesis of β-tubulin, which is rapid and transitory, suggesting a direct role of microtubules in the upregulation of ecdysteroidogenesis by PTTH (Rybczynski and Gilbert, 1995a) (see **Chapter 3.2**). Indeed, microtubule-disrupting drugs inhibit PTTH-stimulated ecdysteroidogenesis in the pupal prothoracic glands (Watson *et al*., 1996). Although the drugs do not inhibit the basal secretory activity of pupal glands, nor PTTH-stimulated larval glands (Gilbert *et al*., 2002), the turnover of cytoskeletal proteins is a possible target of acute feedback inhibition, since vertebrate and insect steroidogenic cells are surprisingly homologous in the mechanisms that regulate the changes in steroidogenesis (Gilbert *et al*., 2002).

A third possibility includes factors that modulate or control, directly or indirectly, the PTTH signaling pathway (see **Chapter 3.2**). PTTH stimulation is known to require *de novo* gene expression and protein synthesis (Keightley *et al*., 1990; Rybczynski and Gilbert, 1994), and the latter may be mediated by S6 kinase (S6K) which mediates ribosomal S6 phosphorylation (Song and Gilbert, 1994, 1995, 1997). Circumstantial evidence deduced from time-course studies indeed shows that PTTH-stimulated S6 phosphorylation is involved in the upregulation of ecdysteroidogenesis. Since S6K activates several transcription factors, including c-Jun and Atf-2, PTTH signaling could involve activation of the transcription factors. Interestingly, the dephosphorylation of S6 protein occurs in temporal synchrony with the decline in ecdysone biosynthesis (Song and Gilbert, 1995), indicating that the feedback inhibition of ecdysteroidogenesis does not necessarily involve the direct inhibition of the enzymes in the ecdysone biosynthetic pathway. Rather, the regulation of the synthesis of proteins that control such enzyme activities could be the primary target of negative feedback regulation by 20E. In PTTH-stimulated prothoracic gland cells, hsp70 synthesis is also upregulated (Rybczynski and Gilbert, 1995b, 2000), implying its participation in feedback control of ecdysteroidogenesis by the modulation of the assembly of the ecdysteroid receptor complex. In this regard, USP proteins are suggested to exert important roles in the negative feedback (Gilbert *et al*., 1997) (see Section 3.8.5). Although not yet identified, molecular chaperones besides hsp70 could also be involved in modulating the rate of ecdysteroidogenesis by assisting the movement into the mitochondria of catalytic enzymes synthesized in the cytosol.

3.8.5. Molecular Mechanism of Feedback Inhibition

3.8.5.1. Feedback Mediated by the EcR/USP Heterodimer

In the feedback inhibition of prothoracic glands, the primary action of 20E is most likely mediated by a heterodimeric nuclear receptor composed of the ecdysone receptor (EcR) and Ultraspiracle (USP) (see **Chapters 3.5** and **3.6**). In this interaction, the USP isoform is of primary importance (Gilbert *et al*., 1997; Song and Gilbert, 1998) (**Figure 3**). Developmental profiles of two USP isoforms in the prothoracic glands of *Manduca* last instar larvae revealed that USP-1 and USP-2 are expressed in complementary patterns. At first, USP-1 is predominant while USP-2 is barely detectable until day 6 at which time the hemolymph ecdysteroid level only begins to rise. After day 6, USP-2 is upregulated and expressed maximally on days 7–9, i.e., during the peak in the ecdysteroid titer, while USP-1 is simultaneously downregulated to almost undetectable levels. The net result is that USP-2 comprises about 85% of the total USP proteins (Gilbert *et al*., 1997). The downregulation of USP-1 and simultaneous upregulation of USP-2, both being elicited by 20E, may alter a set of genes that ultimately leads to downregulation of ecdysteroidogenesis. *In vitro* incubation with 20E inhibits gland activity (**Figure 2**). Incubation of day 5 prothoracic glands with 20E reduced the basal secretory activity in 6 h to one-sixth that of the control glands incubated in medium alone. During the 6 h incubation with 20E, USP-1 is downregulated while USP-2 is upregulated. In day 7 glands, only the EcR/USP-2 heterodimer is present, but not EcR/USP-1, indicating that USP-2 becomes the predominant component of the receptor complex in response to a high ecdysteroid titer, forming EcR/USP-2, presumed to be functional in feedback inhibition (Song and Gilbert, 1998). After the binding of 20E to EcR, the functional heterodimer probably leads to the downregulation of the expression of one or more critical

components of the ecdysteroidogenic pathway (Gilbert *et al.*, 1997). 20E is more effective than ecdysone by a factor of 100 in eliciting the expression of USP-2 in day 5 prothoracic glands. This difference in activity coincides well with the difference in binding affinities of these two ecdysteroids for the EcR/USP complex (Cherbas *et al.*, 1980; Minakuchi *et al.*, 2003) (see **Chapter 3.5**). Such a difference is reflected in the activities of ecdysone and 20E in the *in vitro* feedback inhibition of the prothoracic glands (Sakurai and Williams, 1989). Two EcR isoforms, EcR-A and EcR-B1, have been identified in Lepidoptera. However, it remains to be seen which isoform participates in forming the functional EcR/USP-2 heterodimer and whether the EcR/USP-2 heterodimer is the primary transcriptional factor providing for the downregulation of USP-1.

Although incubation of day 5 *Manduca* prothoracic glands with 20E for 6 h markedly reduces the basal secretory activity, they still retain their responsiveness to PTTH, e.g., as PTTH elicits an activation ratio of 5 (**Figure 2**). This activation ratio, however, decreases from approximately 15 after 1 h incubation with 20E, to 5 after 6 h, indicating that 20E does affect the PTTH signaling pathway. The complementary patterns with USP-2 being predominant during the incubation with 20E could cause the loss of sensitivity to PTTH (Song and Gilbert, 1998), and thereby act to sustain the inhibited state of ecdysteroidogenesis.

It is of interest that the developmental profiles of individual USP isoform expression in epidermis are quite similar to those in the prothoracic glands (Hiruma *et al.*, 1999). USP-1 mRNA levels are high during the feeding period, but decline to low levels shortly after the onset of the wandering stage when the hemolymph ecdysteroid titer begins to increase. In contrast, the USP-2 mRNA level remains low until the increase in ecdysteroid titer, after which its expression is enhanced. A similar control over the expression of USP isoforms by 20E is reported in the adult mosquito *Aedes aegypti* (Wang *et al.*, 2000). After a blood meal, the fat body initiates the production of yolk protein (vitellogenin), needed for egg maturation, in response to 20E originating from the ecdysone secreted by the ovaries that are stimulated by the blood meal (see **Chapter 3.9**). USP-A (*A. aegypti* homolog of USP-1) is downregulated at the time of the increase in 20E titer, while USP-B (homolog of USP-2) is upregulated. Incubation of the fat body with 20E results in the upregulation of USP-B while USP-A transcription is downregulated. EcR/USP-B elicits a stronger transactivating activity on the vitellogenin gene than does EcR/USP-A. The function of the receptor complex, of course, varies among the tissues that exhibit tissue-specific responses to 20E, e.g., the feedback inhibition of ecdysteroidogenesis in the prothoracic glands, the triggering of pupal differentiation in the epidermis, and yolk protein expression in the ovaries. However, the fundamental molecular mechanisms underlying the control of gene expression by EcR/USP could be similar in individual tissues.

We presently have no information to speculate about whether feedback inhibition affects one or more of the enzyme activities involved in the ecdysone biosynthetic pathway. A decrease in ecdysone production may be as important as an increase with respect to the regulation of insect growth and development, but little is known at present about feedback regulation at either the biochemical or molecular levels.

3.8.5.2. Acute and Delayed Inhibition

Incubation of day 5 fifth instar *Manduca* prothoracic glands with 20E for 1 h strongly suppresses the basal secretory activity to about 20% of the control, but the glands retain their competence to respond to PTTH (Song and Gilbert, 1998) (**Figure 2**). Similarly, RH-5849 significantly suppresses the secretory activity within 10 min while retaining sensitivity to PTTH (Sakurai and Gilbert, unpublished data). Acute inhibition is also reported in the crayfish *Orconectes limosus*, in which the Y-organ is the ecdysteroidogenic gland, and 20E injection to the crayfish larvae inhibits the gland activity. Ecdysteroid release from intermolt Y-organs is reduced sixfold within 1 h after 20E injection (Dell *et al.*, 1999). In *Manduca* prothoracic glands, the complementary pattern of USP-1 and USP-2 expression appears only after a 6 h of incubation with 20E, but nothing is observed after only 1 h (Song and Gilbert, 1998). In an injection study in *Orconectes*, the degree of inhibition caused by RH-5849 at its minimum effective dose of 5 μg is less than that resulting from 0.25 μg 20E. Thus, RH-5849 is at least 20 times less effective than 20E. The binding affinity of 20E for the *Chironomus tentans* EcR/USP complex is in the range of 10^{-7} M ($K_d = 230$ nM), and is similar to that of RH-5849 ($K_d = 278$ nM) (Smagghe *et al.*, 2002) (see **Chapter 3.5**). The binding affinities of 20E and RH-5849 to the *in vitro* translated EcR/USP complex of *Chilo suppressalis* shows that 20E affinity is only threefold higher than RH-5849 (Minakuchi *et al.*, 2003). However, it is not obvious whether the direct application of this K_d data to *Orconectes* is appropriate, since the binding affinity of some ecdysteroid agonists differs greatly in different orders of insects, e.g., the binding affinity of RH-2485, another potent nonsteroidal ecdysone

agonist, for crude nuclear extracts is 70-fold higher than that of 20E in the moth *Plodia interpunctella*, while in the beetle *Anthonomus grandis*, the former value is less than the latter by a factor of 50 (Dhadialla and Tzertzinis, 1997). Nevertheless, in *Chironomus*, *Chilo*, and *Orconectes*, in spite of the similarity in the affinities of 20E and RH-5849 to the EcR/USP complex, 20E is 20-fold more effective than RH-5849 in inhibiting ecdysone secretion, indicating that the acute inhibition may not be due to a genomic action of 20E. Hence, the acute inhibition of basal secretory activity indicates that the rapid feedback inhibition of ecdysteroid secretion might be mediated by a nongenomic pathway, rather than a conventional genomic pathway. The acute inhibition does not, however, suppress the prothoracic gland responsiveness to PTTH (Song and Gilbert, 1998).

The above discussion gives rise to a more complex model for the role of feedback inhibition. There may be two different signaling pathways underlying the feedback inhibition; one is acute and the other is delayed. Acute inhibition may result in the rapid decline of ecdysone secretion after the physiological peak concentration of 20E is attained in the hemolymph and is probably mediated by a nongenomic action of 20E. After this acute inhibition, a second genomic action via the EcR/USP-2 heterodimer ensures that the glands will not produce ecdysone again once the 20E titer declines below the threshold level for the acute feedback inhibition. Thereby, the glands are maintained inactive until the next PTTH stimulation. During this period with low secretory activity, developmental events are allowed to occur in response to a declining ecdysteroid concentration.

3.8.6. Horizontal Control of the Prothoracic Gland

20E also affects CA activity while JH alters prothoracic gland ecdysteroidogenic activity (see **Chapter 3.7**). JH is believed to elicit the control of prothoracic gland activity in two ways: one through the control of PTTH release and the other by a direct effect on the glands, although the evidence for this is not yet firm. In addition, JH effects, at least in the last larval instar, change from a primarily static response to a tropic response on the brain–prothoracic gland axis at a time shortly before the onset of wandering (Hiruma *et al*., 1978; Cymborowski and Stolarz, 1979; Safranek *et al*., 1980). In this section, JH effects on PTTH secretion from the brain and ecdysone secretion from the prothoracic glands will be discussed. The effect of ecdysteroids on CA secretory activity is detailed elsewhere (see **Chapter 3.7**).

3.8.6.1. Effects of JH on PTTH Secretion

Injection or topical application of JH or its analogs methoprene (effective in *Bombyx*) or hydroprene (effective in *Manduca*), at an appropriate period during the feeding stage of the last larval instar of Lepidoptera, delays the onset of the prepupal period in *Manduca* (Nijhout and Williams, 1974b; Safranek *et al*., 1980; Rountree and Bollenbacher, 1986; Watson and Bollenbacher, 1988), *Spodoptera littoralis* (Cymborowski and Stolarz, 1979), and *Bombyx* (Akai *et al*., 1973; Sakurai and Imokawa, 1988; Gu *et al*., 1997). In *Manduca*, the prothoracic glands from hydroprene- or JH I-treated larvae are capable of responding to PTTH *in vitro*. Therefore, the delay is supposed to be due to the inhibition of PTTH release from the brains (Rountree and Bollenbacher, 1986). In *Bombyx*, JH analog (JHA) application before day 3 of the fifth instar results in a delay of the onset of wandering, while its application on day 3 produces dauer (permanent) larvae that never undergo metamorphosis, but die after surviving for more than 2 weeks (Akai *et al*., 1973; Sakurai and Imokawa, 1988). In such larvae, the prothoracic glands retain their sensitivity to PTTH, when assessed by an *in vitro* PTTH challenge. In addition, PTTH injection 10 days after the JHA treatment restores spinning behavior and is followed by normal pupation, just as if the days between the JHA treatment and PTTH injection did not exist (Sakurai and Imokawa, 1988). These data indicate that JHA can disturb the program of PTTH secretion in the brain if JHA is applied at a critical time point in the fifth instar.

If JH suppresses PTTH release, then what is the effect of JH on the brain–prothoracic gland axis in the penultimate instar when the JH titer is high? Removal of the corpora allata from early penultimate instar larvae results in the induction of precocious pupation. In *Mamestra* and *Bombyx*, the hemolymph ecdysteroid titer peaks on day 3 of the fourth instar and induces larval ecdysis. Allatectomy abolishes the appearance of the ecdysteroid peak and the ecdysteroid titer remains at low levels for several days until the precocious onset of wandering (Hiruma, 1986; Ohtaki *et al*., 1986). The prothoracic glands, after allatectomy, retain their responsiveness to PTTH, indicating that the decline of the JH titer after allatectomy may act on the brain to alter the PTTH secretion program for larval ecdysis. JH application to the allatectomized larvae increases the hemolymph ecdysteroid concentration (Ohtaki *et al*., 1986), as well as the basal secretory activity of the prothoracic glands within 24 h of the JHA treatment (Sakurai, unpublished data). In

addition, the brains of early penultimate instar larvae of *M. brassicae* contain higher PTTH activity than do those of allatectomized larvae (Hiruma, 1986). This may be due to an accumulation of PTTH in the brain, the result of a declining JH titer suppressing PTTH release. These observations suggest that in the penultimate instar, JH may serve to maintain the brain to produce and/or release PTTH, and the brain ceases PTTH release in the absence of JH in the hemolymph. A similar situation is found in the late feeding stage of the last larval instar of *Manduca* and *Mamestra*. Allatectomy delays their pupation by delaying the appearance of the ecdysteroid peak in the prepupal period (Hiruma, 1986; Sakurai, 1990). This could be interpreted as a result of a delay in PTTH release due to low JH titer, although there are no data documenting either the release of PTTH from the brain, nor the PTTH titer in the hemolymph. Only one instance of the direct measurement of PTTH in the hemolymph is available to assess these effects of JH (Mizoguchi, 2001). On days 0–2 of the last larval instar in *Bombyx*, topically applied JH I increases the PTTH concentration in hemolymph significantly. When day 0 larvae were treated with 3 μg JH I, the PTTH titer increased from 28 to 50 pg ml^{-1} in 12 h. Whether or not this increase is of significant biological meaning, it is at least clear that JH does not inhibit PTTH secretion, even in early fifth instar. This is contrary to the data of Rountree and Bollenbacher (1986) who showed that JH inhibits PTTH release in feeding last instar larvae in *Manduca*. Rather, JH seems to act as a positive regulator of brain PTTH secretion, as has been proposed in *Galleria mellonella* (Sehnal *et al*., 1981). Then, how can we interpret the earlier observations that JH induces dauer larvae or causes a delay in the onset of wandering if applied early in the fifth instar? Induction of dauer larvae require an injection of 10 μg JH I (Akai and Kobayashi, 1971) or 1 μg methoprene (Sakurai and Imokawa, 1988). However, the highest titer of JH in the last instar is less than 10 ng JH I equivalent ml^{-1} (Fain and Riddiford, 1975; Baker *et al*., 1987; Niimi and Sakurai, 1997), which indicates that although the dose of JH is pharmacological, JH nevertheless disturbs the PTTH release program in the brain, directly or indirectly, through an unknown nervous network participating in the control of PTTH cells. Apart from the effects of JH on PTTH release, it is obvious that the brain also responds to an increase and decrease in both ecdysteroid and JH. Quoting Gilbert *et al*. (2000), "ecdysteroids and JHs interact and we cannot study one without considering the other." Ecdysteroids and JH must affect the production and release of PTTH, although the role of JH on the brain is still obscure due to the lack of *in vitro* information on PTTH secretion from the brain.

3.8.6.2. Effects of JH on Ecdysteroidogenesis

Effects of JH on ecdysteroidogenesis are somewhat complicated and not yet understood. JH stimulation of prothoracic gland activity was first demonstrated in diapausing pupae of *H. cecropia*; JH injection broke the diapause (Gilbert and Schneiderman, 1959; Williams, 1959). However, the brain may not be involved in the diapause-terminating effects of JH, since JH effects were observed in pupae whose brains had been removed prior to JH treatment (Gilbert and Schneiderman, 1959). This indicates that the brain of a diapausing pupa is not the primary target of the applied JH. Rather, JH appears to directly stimulate the pupal prothoracic glands.

In *H. cecropia* diapausing pupae (Gilbert and Schneiderman, 1959), JH probably stimulated prothoracic glands to secrete ecdysone so that a positive feedback loop was initiated, operating in a manner similar to that demonstrated for the *Manduca* pupal prothoracic glands (Sakurai and Williams, 1989). In *Manduca* pupae, ecdysteroids stimulate prothoracic glands of diapausing pupae, but also those in a very early nondiapausing pupal stage. Although JH stimulation of pupal prothoracic glands has been demonstrated *in vivo*, JH has not been detected in the pupal stage, at least before degeneration of the prothoracic glands. Thus, JH stimulation of the pupal glands cannot occur in the normal insect life cycle.

In the last larval instar of Lepidoptera, JH delays the increase in the hemolymph ecdysteroid titer when topically applied to prewandering larvae. However, its effect on the steroid titer changes from inhibitory to stimulatory shortly before or at the wandering stage (Hiruma *et al*., 1978; Safranek *et al*., 1980; Sakurai, 1990). In the prepupal stage, JH has been considered to have a stimulatory effect on prothoracic glands. The hemolymph JH titer begins to increase concomitantly with the onset of wandering and reaches a broad peak at the midpoint of the prepupal period, after which it decreases towards pupation (Baker *et al*., 1987; Niimi and Sakurai, 1997). Removal of the corpora allata from the last instar larvae during the prewandering stage results in a delay of pupation in *Mamestra* and *Manduca* (Hiruma, 1980; Hiruma *et al*., 1999), indicating that the JH peak may affect ecdysteroidogenesis. Neck ligation of *Manduca* feeding larvae on the day of wandering suppresses pupation, and JHA (hydroprene) application restores the delay (Safranek *et al*., 1980). The ligation suppressed the

increase in hemolymph ecdysteroid titer after wandering, while the administration of JHA to those larvae increased these levels to that found in intact larvae. However, *in vitro* treatment of wandering larval glands with JHA fails to stimulate gland activity (Sakurai, 1990).
